ASM HANDBOOK®

VOLUME
7

*Powder Metal
Technologies
and
Applications*

Publication Information and Contributors

Powder Metal Technologies and Applications was published in 1998 as Volume 7 of *ASM Handbook*. The Volume was prepared under the direction of the ASM Handbook Committee.

Editorial Advisory Board

- **Peter W. Lee** The Timken Co.
- **Yves Trudel** Quebec Metal Powders Limited
- **Ronald Iacocca** The Pennsylvania State University

Foreword

In recognition of the ongoing development and growth of powder metallurgy (P/M) materials, methods, and applications, ASM International offers the new Volume 7 of *ASM Handbook. Powder Metal Technologies and Applications* is a completely revised and updated edition of *Powder Metallurgy*, Volume 7 of the 9th Edition *Metals Handbook*, published in 1984. This new volume provides comprehensive updates that reflect the continuing improvements in traditional P/M technologies as well as significant new coverage of emerging P/M materials and manufacturing methods.

The ASM Handbook Committee, the editors, the authors, and the reviewers have collaborated to produce a book that meets the high technical standards of the *ASM Handbook* series. In addition to in-depth articles on production, testing and characterization, and consolidation of powders, the new volume expands coverage on the performance of P/M materials, part shaping methods, secondary operations, and advanced areas of engineering research such as process modeling. This extensive coverage is designed to foster increased awareness of the current status and potential of P/M technologies. To all who contributed toward the completion of this task, we extend our sincere thanks.

Alton D. Romig, Jr.

President, ASM International

Michael J. DeHaemer

Managing Director, ASM International

Preface

On behalf of the ASM Handbook Committee, it is a pleasure to introduce this fully revised and updated edition of Volume 7, *Powder Metal Technologies and Applications* as part of the *ASM Handbook* series. Since the first publication of Volume 7 in 1984 as part of the 9th Edition *Metals Handbook*, substantial new methods, technologies, and applications have occurred in powder metallurgy. These developments reflect the continuing growth of powder metallurgy (P/M) as a technology for net-shape fabrication, new materials, and innovative manufacturing processes and engineering practices.

Net-shape or near-net-shape fabrication is a key objective in many P/M applications. Many factors influence the economics and performance of P/M fabrication, and new methods and process improvements are constantly considered and developed. In this regard, the new Volume 7 provides completely updated information on several emerging technologies for powder shaping and consolidation. Examples include all new articles on powder injection molding, binder assisted extrusion, warm compaction, spray forming, powder extrusion, pneumatic isostatic forging, field activated sintering, cold sintering, and the consolidation of ultrafine and nanocrystalline materials. New articles also cover process modeling of injection molding, isostatic pressing, and rigid die compaction.

Traditional press-and-sinter fabrication and high-density consolidation remain the major topic areas in the new Volume 7. This coverage includes new articles in several practical areas such as resin impregnation, dimensional control, machining, welding, heat treatment, and metallography of P/M materials. The traditional processes of rigid die compaction and sintering are also covered extensively with several updated articles on major production factors such as tooling, die design, compressibility and compaction, sintering practices, and atmosphere control. An overview article, "Powder Shaping and Consolidation Technologies," also compares and summarizes the alternatives and factors that can influence the selection of a P/M manufacturing method. Coverage is also expanded on high-density consolidation and high-performance P/M materials such as powder forged steels.

Multiple articles on powder production and characterization methods have also been revised or updated in several key areas. The article on atomization is fully revised from the previous edition, and several new articles have been added to the Section "Metal Powder Production and Characterization." In particular, the new article by T. Allen, "Powder Sampling and Classification," is a key addition that provides essential information for accurate characterization of particle size distributions. The variability of sieve analysis is also covered in more detail in this new Volume.

The new Volume 7 also provides detailed performance and processing information on a wide range of advanced and conventional P/M materials. Ferrous P/M materials are covered in several separate articles, and more detailed information on corrosion, wear, fatigue, and mechanical properties are discussed in separate articles. New articles also provide information on several advanced materials such as aluminum-base composites and reactive-sintered intermetallics.

This extensive volume would not have been possible without the guidance of the section editors and the dedicated efforts of the contributing authors. I would also like to thank Erhard Klar for organizing the previous edition, which formed the core for the structure of the new edition.

Finally, special thanks are extended to ASM staff--particularly to project editor Steve Lampman--for their dedicated efforts in developing and producing this Volume.

Peter W. Lee

Member, ASM Handbook Committee

General Information

Officers and Trustees of ASM International (1997-1998)

Officers

- **Alton D. Romig, Jr.** President and Trustee Sandia National Laboratories
- **Hans H. Portisch** Vice President and Trustee Krupp VDM Austria GmbH
- **Michael J. DeHaemer** Secretary and Managing Director ASM International
- **W. Raymond Cribb** Treasurer Brush Wellman Inc.
- **George Krauss** Immediate Past President Colorado School of Mines

Trustees

- **Nicholas F. Fiore** Carpenter Technology Corporation
- **Gerald G. Hoeft** Caterpillar Inc.
- **Jennie S. Hwang** H-Technologies Group Inc.
- **Thomas F. McCardle** Kolene Corporation
- **Bhakta B. Rath** U.S. Naval Research Laboratory
- **C. (Ravi) Ravindran** Ryerson Polytechnic University
- **Darrell W. Smith** Michigan Technological University
- **Leo G. Thompson** Lindberg Corporation
- **James C. Williams** GE Aircraft Engines

Members of the ASM Handbook Committee (1997-1998)

- **Michelle M. Gauthier** (Chair 1997-; Member 1990-) Raytheon Electronic Systems
- **Craig V. Darragh** (Vice Chair 1997-; Member 1989-) The Timken Company
- **Bruce P. Bardes** (1993-) Materials Technology Solutions Company
- **Rodney R. Boyer** (1982-1985; 1995-) Boeing Commercial Airplane Group
- **Toni M. Brugger** (1993-) Carpenter Technology Corporation
- **R. Chattopadhyay** (1996-) Consultant
- **Rosalind P. Cheslock** (1994-)
- **Aicha Elshabini-Riad** (1990-) Virginia Polytechnic Institute & State University
- **Henry E. Fairman** (1993-) MQS Inspection Inc.
- **Michael T. Hahn** (1995-) Northrop Grumman Corporation

- **Larry D. Hanke** (1994-) Materials Evaluation and Engineering Inc.
- **Jeffrey A. Hawk** (1997-) U.S. Department of Energy
- **Dennis D. Huffman** (1982-) The Timken Company
- **S. Jim Ibarra, Jr.** (1991-) Amoco Corporation
- **Dwight Janoff** (1995-) FMC Corporation
- **Paul J. Kovach** (1995-) Stress Engineering Services Inc.
- **Peter W. Lee** (1990-) The Timken Company
- **William L. Mankins** (1989-)
- **Mahi Sahoo** (1993-) CANMET
- **Wilbur C. Simmons** (1993-) Army Research Office
- **Karl P. Staudhammer** (1997-) Los Alamos National Laboratory
- **Kenneth B. Tator** (1991-) KTA-Tator Inc.
- **Malcolm C. Thomas** (1993-) Allison Engine Company
- **George F. Vander Voort** (1997-) Buehler Ltd.

Previous Chairmen of the ASM Handbook Committee

- **R.J. Austin** (1992-1994) (Member 1984-)
- **L.B. Case** (1931-1933) (Member 1927-1933)
- **T.D. Cooper** (1984-1986) (Member 1981-1986)
- **E.O. Dixon** (1952-1954) (Member 1947-1955)
- **R.L. Dowdell** (1938-1939) (Member 1935-1939)
- **J.P. Gill** (1937) (Member 1934-1937)
- **J.D. Graham** (1966-1968) (Member 1961-1970)
- **J.F. Harper** (1923-1926) (Member 1923-1926)
- **C.H. Herty, Jr.** (1934-1936) (Member 1930-1936)
- **D.D. Huffman** (1986-1990) (Member 1982-)
- **J.B. Johnson** (1948-1951) (Member 1944-1951)
- **L.J. Korb** (1983) (Member 1978-1983)
- **R.W.E. Leiter** (1962-1963) (Member 1955-1958, 1960-1964)
- **G.V. Luerssen** (1943-1947) (Member 1942-1947)
- **G.N. Maniar** (1979-1980) (Member 1974-1980)
- **W.L. Mankins** (1994-1997) (Member 1989-)
- **J.L. McCall** (1982) (Member 1977-1982)
- **W.J. Merten** (1927-1930) (Member 1923-1933)
- **D.L. Olson** (1990-1992) (Member 1982-1988, 1989-1992)
- **N.E. Promisel** (1955-1961) (Member 1954-1963)
- **G.J. Shubat** (1973-1975) (Member 1966-1975)
- **W.A. Stadtler** (1969-1972) (Member 1962-1972)
- **R. Ward** (1976-1978) (Member 1972-1978)
- **M.G.H. Wells** (1981) (Member 1976-1981)
- **D.J. Wright** (1964-1965) (Member 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Steven R. Lampman, Project Editor; Grace M. Davidson, Manager of Handbook Production; Bonnie R. Sanders, Copy Editing Manager; Alexandra B. Hoskins, Copy Editor; Randall L. Boring, Production Coordinator; and Kathleen S. Dragolich, Production Coordinator. Editorial assistance was provided by Amy E. Hammel and Anita D. Fill. The Volume was prepared under the direction of Scott D. Henry, Assistant Director of Reference Publications, and William W. Scott, Jr., Director of Technical Publications.

Conversion to Electronic Files

ASM Handbook, Volume 7, *Powder Metal Technologies and Applications* was converted to electronic files in 1999. The conversion was based on the first printing (1998). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Introduction

POWDER METALLURGY has been called a lost art. Unlike clay and other ceramic materials, the art of molding and firing practical or decorative metallic objects was only occasionally applied during the early stages of recorded history. Sintering of metals was entirely forgotten during the succeeding centuries, only to be revived in Europe at the end of the 18th century, when various methods of platinum powder production were recorded (Table 1).

Table 1 Major historical developments in powder metallurgy

Date	Development	Origin
3000 B.C.	"Sponge iron" for making tools	Egypt, Africa, India
A.D. 1200	Cementing platinum grains	South America (Incas)
1781	Fusible platinum-arsenic alloy	France, Germany
1790	Production of platinum-arsenic chemical vessels commercially	France
1822	Platinum powder formed into solid ingot	France
1826	High-temperature sintering of platinum powder compacts on a commercial basis	Russia
1829	Wollaston method of producing compact platinum from platinum sponge (basis of modern P/M technique)	England
1830	Sintering compacts of various metals	Europe
1859	Platinum fusion process	
1870	Patent for bearing materials made from metal powders (forerunner of self-lubricating bearings)	United States
1878-1900	Incandescent lamp filaments	United States
1915-1930	Cemented carbides	Germany
Early 1900s	Composite metals	United States
	Porous metals and metallic filters	United States

1920s	Self-lubricating bearings (used commercially)	United States
1940s	Iron powder technology	Central Europe
1950s and 1960s	P/M wrought and dispersion-strengthened products, including P/M forgings	United States
1970s	Hot isostatic pressing, P/M tool steels, and superplastic superalloys	United States
1980s	Rapid solidification and powder injection molding technology	United States
1990s	Intermetallics, metal-matrix composites, spray forming, nanoscale powders, and warm compaction	United States, England

Metal powders such as gold, copper, and bronze, and many powdered oxides (particularly iron oxide and other oxides used as pigments), were used for decorative purposes in ceramics, as bases for paints and inks, and in cosmetics since the beginnings of recorded history. Powdered gold was used to illustrate some of the earliest manuscripts. It is not known how these powders were produced, but it is possible that some of the powders were obtained by granulation after the metal was melted. Low melting points and resistance to oxidation (tarnishing) favored such procedures, especially in the case of gold powder. The use of these powders for pigments and ornamental purposes is not true powder metallurgy, because the essential features of the modern art are the production of powder and its consolidation into a solid form by the application of pressure and heat at a temperature below the melting point of the major constituent.

Early man learned by chance that particles of metal could be joined together by hammering, resulting in a solid metallic structure. In time, man learned how to build furnaces and develop temperatures high enough to melt and cast metals and to form lower melting alloys, such as copper and tin to make bronze.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Earliest Developments

Long before furnaces were developed that could approach the melting point of metal, P/M principles were used. About 3000 B.C., the Egyptians used a "sponge iron" for making tools. In this early process, iron oxide was heated in a charcoal and crushed shell fire, which was intensified by air blasts from bellows to reduce the oxide to a spongy metallic iron. The resulting hot sponge iron was then hammered to weld the particles together. Final shapes were obtained by simple forging procedures. Although the product often contained large amounts of nonmetallic impurities, some remarkably solid and sound structures have been discovered (Ref 1).

W.D. Jones (Ref 2) wrote of a process modification developed by African tribes. After reduction, the sponge was broken into powder particles, washed, and sorted by hand to remove as much of the slag and gangue as possible. The powder was then either compacted or sintered into a porous material, which was subsequently forged. Another example of ancient reduction of iron oxide was carried out in the fabrication of the Delhi Pillar, which weighs 5.9 metric tons (6.5 tons).

These crude forms of powder metallurgy ultimately led to the development of one of the commercial methods for producing iron powder. By grinding the sponge iron into fine particles, and heating in hydrogen to remove oxides and anneal or soften the particles, this process is today a viable technique for producing high-quality iron powder.

Powder metallurgy practices were used by the Incas and their predecessors in making platinum before Columbus made his voyage to the "New World" in 1492. The technique used was based on the cementing action of a lower melting binder, a technique similar to the present practice of making sintered carbides.

The technique consisted of cementing platinum grains (separated from the ore by washing and selection) by the addition of an oxidation-resistant gold-silver alloy of a fairly low melting point to wet the grains, drawing them together by surface tension and forming a raw ingot suitable for further handling (Ref 3).

A color change from the yellow of the sintered material to the whitish platinum of the final metal was caused by diffusion during heating prior to working. Heating is thought to have been accomplished by means of charcoal fires fanned by blowpipes. Analyses of these alloys vary considerably. The platinum content ranged from 26 to 72%, and the gold content ranged from 16 to 64%. Silver additions were found to vary from 3 to 15%, and amounts of copper up to 4% were traced.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Powder Metallurgy of Platinum

The metallurgy of platinum, as practiced in the 18th and 19th centuries in Europe, is considered to be one of the most important stages of development for modern powder metallurgy. For the first time, complete records were available that provided insight into the various methods of powder production and the processing of these powders into solid, useful implements.

Between 1750 and 1825, considerable attention was given to the manufacture of platinum. In 1755, Lewis (Ref 4) discovered that when a lead-platinum alloy was oxidized at high temperatures, a spongy, workable mass remained after lead oxide impurities had been volatilized. Scheffer (Ref 5) found that when platinum was heated with arsenic, the platinum showed signs of melting. This finding was confirmed in 1781 by Achard (Ref 6), who described the production of a fusible platinum-arsenic alloy, probably by forming the eutectic containing 87% Pt and melting at 600 °C (1110 °F). Achard formed solid platinum by hot hammering a sponge, welding the individual particles into a large solid. The sponge was obtained by high-temperature working of the platinum-arsenic alloy, which caused volatilization of the arsenic.

This procedure formed the basis for a method of producing platinum that was first used in about 1790 in commercially manufactured chemical vessels by Jannetty in Paris. Mercury was used later in a similar process by von Mussin-Puschkin (Ref 7). Other metals worked in this way include palladium, by using sulfur instead of arsenic, and iridium (using phosphorus). Ridolfi (Ref 8) made malleable platinum for chemical vessels using lead and sulfur.

In 1786, Rochon (Ref 9) successfully produced solid platinum without using arsenic by welding small pieces of scrap platinum. He produced malleable platinum by uniting purified platinum grains.

Knight (Ref 10) found that if chemically precipitated platinum powder was heated at high temperatures in a clay crucible, it softened and could be compressed and forged. Tilloch (Ref 11) put platinum powder into tubes made of rolled platinum sheet, which were then heated and forged to produce a compact mass. In 1813, Leithner (Ref 12) reported production of thin, malleable platinum sheets by drying out successive layers of powder suspended in turpentine and heating the resulting films at high temperatures without pressure.

In 1882, a French process was reported by Baruel (Ref 13), in which 14 kg (30 lb) of platinum powder was made into a solid ingot by a series of operations. Platinum was precipitated in powdered form, slightly compressed in a crucible, and heated to white heat. The powder was then put in a steel matrix and put under pressure with a screw coining press. The compact platinum was repeatedly reheated and re-pressed until a solid ingot was formed. The final heat treatments were made in a charcoal fire at lower temperatures. Because the platinum powder was placed in the steel die while hot, this process was based on the hot pressing technique.

In Russia in 1826, a high-temperature sintering operation was applied to previously compressed powder compacts on a commercial basis for the first time. This was in contrast to methods based on hot pressing. Sobolewskoy (Ref 14) described sifted platinum powder pressed into a cast iron cylinder that featured a steel punch actuated by a screw press.

The resulting compacts were annealed for $1\frac{1}{2}$ days at high temperature in a porcelain firing kiln. The final product was highly workable, especially if the platinum powder had been well washed and was of high purity. Annealing, however, caused a decrease in volume; a cylinder 100 mm (4 in.) in diameter and 19 mm ($\frac{3}{4}$ in.) in height shrank 19 mm ($\frac{3}{4}$ in.) and 6 mm ($\frac{1}{4}$ in.) in these dimensions, respectively.

Another Russian method was reported by Marshall (Ref 15) in 1832. Platinum powder in a ring-shaped iron mold was pressed by a screw press, heated to a red heat, and re-pressed. After working in a rolling mill, the compacted discs were used as coins.

The Wollaston process of producing compact platinum from platinum sponge powder is generally considered the beginning of modern powder metallurgy. At least 16 years prior to his publication of 1829 (Ref 16), describing the manufacture of a product much superior to that of contemporary manufacturers, Wollaston devised the foundations for modern P/M technique. Wollaston was the first to realize all the difficulties connected with the production of solid platinum ingot from powdered metal, and thus concentrated on the preparation of the powder. He found that pressing the powder while wet into a hard cake (to be subsequently baked at red heat) was best done under considerable pressure. In addition, because available screw presses were not powerful enough, Wollaston developed a horizontal toggle press of the simple construction shown in Fig. 1. Wollaston used the following nine steps in the manufacture of compact platinum metal (Ref 17):

1. Precipitating ammonium-platinum-chloride from diluted solutions
2. Slowly decomposing the finely divided and carefully washed ammonium-platinum-chloride precipitate into loose sponge powder
3. Grinding this sponge powder without applying pressure to the powder particles, thus avoiding any burnishing of the particles and preserving all the surface energy of the particles
4. Sieving the sponge powder
5. Washing the sponge powder with water to remove all remnants of volatile salts
6. Separating fine particles from coarser particles through sedimentation (only the finest sponge particles were used)
7. Pressing the wet mass containing the finest platinum particles into a cylindrical cake
8. Drying the wet cake very slowly and then heating it to about 800 to 1000 °C (1475 to 1830 °F)
9. Forging the cake while it was still hot

Fig. 1 Simple toggle press used by Wollaston for making platinum powder compacts

By applying these steps, Wollaston succeeded in producing compact platinum, which when rolled into thin sheet was practically free of gas blisters. Crucibles made from this sheet were the best quality platinum implements of their time. Wollaston's process was used for more than a generation and became obsolete only with the advent of the platinum fusion procedure developed by Sainte-Claire Deville and Debray in 1859 (Ref 17). They succeeded in producing a powerful flame with illuminating gas and oxygen, the oxygen being manufactured from manganese dioxide. However, the fused metal which they produced was superior to Wollaston platinum in quality and homogeneity, and the fusion procedure was also less expensive and quicker than the Wollaston method. Fusion, therefore, was soon adopted by every platinum refinery. It is still considered the superior method for manufacturing standard-quality platinum.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Further Developments

The use of P/M technology to form intricately shaped parts by pressing and sintering was introduced in the 19th century. In 1830, while determining the atomic weight of copper, Osann (Ref 18) found that the reduced metal could be sintered into a compact. Osann then developed a process for making impressions of coins from copper powder produced by the reduction of precipitated copper carbonate (Cu_2CO_3).

Osann found that reduction was best done at the lowest possible temperatures that could be used to produce a metal powder of the fineness known in platinum manufacture. High reduction temperatures resulted in granular masses that did not sinter well. Contamination of the powder by the atmosphere was eliminated by using the powder immediately after reduction or storing it in closed glass bottles. The powder was separated into three grades, determined by particle size, before use. To make an impression of a coin, fine powder was sprayed on the surface, followed by layers of coarser grades. The powder and a die were placed in a ring-shaped mold and compressed by the pressure of hammer blows on a punch or use of a knuckle press. Volume of the copper powder was reduced to one-sixth of the original powder during compression. Sintering was done at temperatures close to the melting point of copper, after the compacts were placed in airtight copper packets sealed with clay. A nondistorted 20% shrinkage occurred, but the sintered copper was harder and stronger than cast copper.

Osann also produced medals of silver, lead, and copper by the same procedure. Although he considered his process especially suitable as an alternative to the electrotype method of reproducing coins and medallions, Osann advocated its use as an initial production method for these articles. He believed powder metallurgy could be used for producing printing type and for making convex and concave mirrors by pressing on glass. Osann thought that measurement of the shrinkage of copper compacts could be used to calculate temperature, as the shrinkage of clay cylinders was used in the Wedgewood pyrometer.

Among the advancements in the P/M industry during the second half of the 19th century were Gwynn's attempts to develop bearing materials from metal powders. Patents issued to Gwynn in 1870 (Ref 19) were the forerunners of a series of developments in the area of self-lubricating bearings. Gwynn employed a mixture of 99 parts of powdered tin, prepared by rasping or filing, and 1 part of petroleum-still residue. The two constituents were stirred while being heated. A solid form of desired shape was then produced by subjecting the mixture to extreme pressure while enclosing it in a mold. The patent specifically states that journal boxes made by this method or lined with material thus produced would permit shafts to run at high speeds without using any other lubrication.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Commercial Developments

The first commercial application of powder metallurgy occurred when carbon, and later osmium, zirconium, vanadium, tantalum, and tungsten, was used for incandescent lamp filaments. Methods were developed from 1878 to 1898 for making carbon filaments by the extrusion and subsequent sintering of carbonaceous materials.

Osmium filaments were used for a short time from 1898 to 1900. Auer von Welsbach (Ref 20) described the production of filaments of osmium by chemical precipitation of the powder and formation of a mixture with sugar syrup, which served both as binder and, if osmium oxide powder was used instead of the metal, as reducing agent as well. The mixture was squirted through fine dies, and the resulting fine threads were subsequently fired in protective atmospheres to carburize and volatilize the binder, reduce the oxide, and sinter the metal particles into a coherent metallic wire for use as an electrical conductor.

The osmium electric lamp was soon succeeded by tantalum filament lights, which were used widely from 1903 to 1911. The general procedure (Ref 21) was similar to that used for osmium, with the exception that tantalum had to be purified by a vacuum treatment to become ductile. Similar techniques were used for the production of filaments from zirconium, vanadium, and tungsten; with tungsten, especially, extruded wires were bent into hairpin shapes before sintering to shape them for use as filaments. Because lack of ductility was the major shortcoming of these filaments, attempts were made to improve this property by the addition of a few percent of a lower-melting, ductile metal. Tungsten powder was mixed with 2 to 3% Ni, pressed into a compact, and sintered in hydrogen at a temperature slightly below the melting point of nickel. The resulting bars could be drawn, and nickel was removed from the final filaments by a vacuum heat treatment at a high temperature (Ref 22). Although this process was not commercially successful, it was an important step toward the industrial development of cemented carbides and composite materials.

Tungsten was soon recognized as the best material for lamp filaments. The problem, however, was to devise an economical procedure for producing these filaments in large quantities. A number of procedures to produce powdered tungsten had been worked out earlier. In 1783, the D'Elhujar brothers (Ref 23) first produced tungsten powder by heating a mixture of tungstic acid and powdered charcoal, cooling the mixture, and removing the small cake, which crumbled to a powder of globular particles. The purification of tungsten powder by boiling, scrubbing, and skimming to remove soluble salts, iron oxide, clay, and compounds of calcium and magnesium was reported by Polte (Ref 24).

Coolidge Process. At the beginning of the 20th century, Coolidge (Ref 25) made the important discovery that tungsten could be worked in a certain temperature range and would retain its ductility at room temperature. Few changes have been made over the years on the Coolidge procedure; it is still the standard method of producing incandescent lamp filaments. In this method, very fine tungsten oxide powder, WO_3 , is reduced by hydrogen. The powder is pressed into compacts, which are presintered at 1200 °C (2190 °F) to strengthen them so that they can be clamped into contacts. They receive a final sintering treatment near 3000 °C (5430 °F) by passing a low-voltage, high-current density current through the compacts. During sintering, the compacts shrink and reach a density near 90% that of solid tungsten. The sintered compacts can be worked only at temperatures near 2000 °C (3630 °F). When heated to this temperature, they can be swaged into rounds. With increasing amounts of warm work, tungsten becomes more ductile, the swaging temperature can be progressively lowered, and the swaged bars can be drawn into fine wire at relatively low temperatures.

Other Refractory Metals. The procedures developed for the production of tungsten often were adaptable to the manufacture of molybdenum. Lederer (Ref 26) developed a method of making molybdenum using powdered molybdenum sulfide. The sulfide, mixed with amorphous sulfur and kneaded into a paste, was formed into a filament. When exposed to air, the filaments became strong enough to be placed in a furnace. Heating in hydrogen resulted in formation of hydrogen sulfide and sintering of the metal into solid filaments. A similar process was patented by Oberländer (Ref 27), who used molybdenum chloride and other halides as starting materials. When the chloride was treated with a reducing agent such as ether, a paste was obtained.

Tungsten, molybdenum, and tantalum are the three most important refractory metals used today in the lamp, aerospace, electronics, x-ray, and chemical industries. Other refractory metals of minor significance were developed by the P/M

method in the early 1900s, notably niobium, thorium, and titanium. However, at the same time another development, originating in refractory metal processing, took form and rapidly grew to such importance that it far overshadows the parent field. Cemented carbides have become one of the greatest industrial developments of the century.

Cemented Carbides. Ordinary drawing dies were unsatisfactory for drawing tungsten wires and filaments. The need for a harder material to withstand greater wear became urgent. Because it was known that tungsten granules combined readily with carbon at high temperatures to give an extremely hard compound, this material was used as the basis for a very hard, durable tool material known as cemented carbide. The tungsten carbide particles, present in the form of finely divided, hard, strong particles, are bonded into a solid body with the aid of a metallic cementing agent. Early experiments with a number of metals established that this cementing agent had to possess the following properties to permit solidification of the hard metal body:

- Close chemical affinity for the carbide particles
- A relatively low melting point
- Limited ability to alloy with the carbide
- Great ductility (not to be impaired by the cementing operation)

Cobalt satisfied these requirements most closely. The early work was carried out mainly in Germany by Lohmann and Voigtländer (Ref 28) in 1914, by Liebmann and Laise (Ref 29) in 1917, and by Schröter (Ref 30) from 1923 to 1925. Krupp (Ref 31) perfected the process in 1927 and marketed the first product of commercial importance, "Widia." In 1928 this material was introduced to the United States, and the General Electric Company, which held the American patent rights, issued a number of licenses. The process entails carefully controlled powder manufacture, briquetting a mixture of carbide and metallic binder (usually 3 to 13% Co), and sintering in a protective atmosphere at a temperature high enough to allow fusion of the cobalt and partial alloying with the tungsten carbide. The molten matrix of cobalt and partly dissolved tungsten carbide forms a bond, holding the hard particles together and giving the metallic body sufficient toughness, ductility, and strength to permit its effective use as tool material.

Composite Metals. The next development in powder metallurgy was the production of composite metals used for heavy-duty contacts, electrodes, counterweights, and radium containers. All of these composite materials contain refractory metal particles, usually tungsten, and a cementing material with a lower melting point, present in various proportions. Copper, copper alloys, and silver are frequently used; cobalt, iron, and nickel are used less frequently. Some combinations also contain graphite. The first attempt to produce such materials was recorded in the patent of Viertel and Egly (Ref 32) issued shortly after 1900. The procedures used either were similar to those developed for the hard metals (Ref 33) or called for introduction of the binder in liquid form by dipping or infiltration. In 1916, Gebauer (Ref 34) developed such a procedure, which was developed further by Baumhauer (Ref 35) and Gillette (Ref 36) in 1924. Pfanstiehl (Ref 37) obtained patent protection in 1919 for a heavy metal, consisting of tungsten and a binder that contained copper and nickel.

Porous Metal Bearings and Filters. In addition to the development of refractory metals and their carbides, another important area of powder metallurgy that gained attention during the early 1900s was that of porous metal bearings. Special types of these porous bearings are referred to as self-lubricating.

The modern types of bearings, usually made of copper, tin, and graphite powders and impregnated with oil, were first developed in processes patented by Loewendahl (Ref 38) and Gilson (Ref 39 and 40). Gilson's material was a bronze structure, in which finely divided graphite inclusions were uniformly distributed. It was produced by mixing powdered copper and tin oxides with graphite, compressing the mixture, and heating it to a temperature at which the oxides were reduced by the graphite and the copper and tin could diffuse sufficiently to give a bronzelike structure. Excess graphite (up to 40 vol%) was uniformly distributed through this structure. The porosity was sufficient to allow for the introduction of at least 2% oil. The process was later improved by Boegehold and Williams (Ref 41), Claus (Ref 42), and many others, primarily by utilization of elemental metal powders rather than oxides.

Metallic filters were the next stage in the development of these porous metals, and patents date back as far as 1923 (Ref 43), when Claus patented a process and machine to mold porous bodies from granular powder.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Post-War Developments

Infiltration techniques, porous materials, iron powder cores for ratio tuning devices, P/M permanent magnets, and W-Cu-Ni heavy metal compositions were developed during the periods between 1900, World War I, and the late 1920s. At the beginning of World War II in Europe, iron powder technology began its advance to commercial viability. The most spectacular development of iron parts made by powder metallurgy was during World War II in central Europe, where paraffin-impregnated sintered iron driving bands for military projectiles were extensively used. German powder metallurgists found this technique effective as a substitute for scarce gilding metal, a copper-zinc alloy containing 5 to 10% Zn. Production reached a peak of 3175 metric tons (3500 tons) per month for this application.

The advent of mass production in the automotive industry made possible the use of iron and copper powders in large tonnages and spawned many of the technological advances of the modern P/M industry. The automobile has been the basis for most industrial applications of P/M, even in fields unrelated to the automotive industry. The first commercial application of a P/M product, the self-lubricating bearing, was used in an automobile in 1927. It was made from a combination of copper and tin powders to produce a porous bronze bearing capable of retaining oil within its pores by capillary attraction. At about the same time, self-lubricating bearings were introduced to the home appliance market as a refrigerator compressor component.

Through the 1940s and early 1950s, copper powder and the self-lubricating bearing were the principal products of powder metallurgy. Since then, iron powder and steel P/M mechanical components such as gears, cams, and other structural shapes have become dominant. While copper powder remains an important P/M material, consumed on the order of 21,000 metric tons (23,000 tons) per year, it is overshadowed by iron and iron-base powders with markets of 318,000 metric tons (350,000 tons) per year.

Since the end of World War II, and especially with the advent of aerospace and nuclear technology, developments have been widespread with regard to the powder metallurgy of refractory and reactive metals such as tungsten, molybdenum, niobium, titanium, and tantalum and of nuclear metals such as beryllium, uranium, zirconium, and thorium.

All of the refractory metals are recovered from their ores, processed, and formed using P/M techniques. With the reactive metals, powder metallurgy is often used to achieve higher purity or to combine them with other metals or nonmetallics to achieve special properties. Nuclear power plants use fuel elements often made by dispersing uranium oxide in a metal powder (aluminum, for example) matrix. The control rods and neutron shielding may use boron powder in a matrix of nickel, copper, iron, or aluminum. Tungsten combined with nickel and copper powders is used widely as a shielding component in applications where intricate configuration involving machining is required, such as in cobalt-60 containers. In aerospace, beryllium and titanium are used extensively. Rocket skirts, cones, and heat shields are often formed from niobium. Molybdenum is widely used in missile and rocket engine components. Nozzles for rockets used in orbiting space vehicles often are made from tungsten via the P/M process in order to maintain critical dimensional tolerances.

The 1950s and 1960s witnessed the emergence of P/M wrought products. These are fully dense metal systems that began as powders. Hot isostatically pressed superalloys, P/M forgings, P/M tool steels, roll compacted strip, and dispersion-strengthened copper are all examples. Each of these processes and materials is covered in separate articles in this Volume.

The commercialization of powder-based high-performance material emerged as a major breakthrough in metalworking technology in the 1970s by opening up new markets through superior performance, coupled with the cost effectiveness of material conservation and longer operational life.

History of Powder Metallurgy

Revised by Donald G. White, Metal Powder Industries Federation and APMI International

Recent Developments

In the late 1970s, the experimental programs involving P/M wrought products began spilling over into the commercial industrial sector, principally in the form of P/M tool steels and P/M forgings. With the advent of P/M forgings, no longer were properties compromised by density. Fully dense components capable of combining the alloying flexibility and the net and near-net design features of powder metallurgy were very marketable. The later 1970s and early 1980s witnessed a significant metallurgical breakthrough in the recognition of P/M techniques for eliminating segregation and ensuring a fully homogeneous, fine-grained, pore-free, high-alloy structure. Categorized as P/M wrought metals, they led to the perfection of extremely high-purity metal powders and improved consolidation techniques such as hot isostatic pressing (HIP). The 1980s also saw the commercialization of ultrarapid solidification and injection molding technology. Both of these developments are also covered in separate articles in this Volume.

Commercial powder metallurgy now spans the density spectrum from highly porous metal filters through self-lubricating bearings and P/M parts with controlled density to fully dense P/M wrought metal systems. The P/M parts and products industry in North America has estimated sales of more than \$3 billion. It comprises 150 companies that make conventional P/M parts and products from iron- and copper-base powders and about 50 companies that make specialty P/M products such as superalloys, tool steels, porous products, friction materials, strip for electronic applications, high-strength permanent magnets, magnetic powder cores and ferrites, tungsten carbide cutting tools and wear parts, rapid solidification rate (RSR) products, and metal injection molded parts and tool steels. Powder metallurgy is international in scope with growing industries in all of the major industrialized countries. The value of U.S. metal powder shipments (including paste and flake) was \$1.854 billion in 1995. Annual worldwide metal powder production exceeds 1 million tons.

Trends and new developments include:

- Improved manufacturing processes such as HIP, P/M forging, metal injection molding (MIM), and direct powder rolling through increased scientific investigation of P/M technology by government, academic, and industrial research and development programs
- Fully dense P/M products for improved strength properties and quality in automobiles, diesel and turbine engines, aircraft parts, and industrial cutting and forming tools
- Commercialization of technologies such as MIM, rapid solidification, P/M forging, spray forming, high-temperature vacuum sintering, warm compacting, and both cold and hot isostatic pressing
- The use of P/M hot-forged connecting rods in automobiles and a P/M camshaft for four- and eight-cylinder automobile engines. The use of P/M composite camshafts in automotive engines and main bearing caps

A review of major historical developments in powder metallurgy is presented in Table 1.

Powder Metallurgy Literature

A number of literary works are worthy of mention in connection with the background of powder metallurgy. One of the earliest works of significance was *Principles of Powder Metallurgy* by W.D. Jones, published in 1937 in England (Ref 44). It was updated in 1960 and published as *Fundamental Principles of Powder Metallurgy* (Ref 45). The first Russian publication was by Bal'shin (Ref 46) and appeared in 1938; the first comprehensive text in German, *Pulvermetallurgie und Sinterwerkstoffe*, was published by R. Kieffer and W. Hotop in 1943 (Ref 47). In the United States, the first publication was by H.H. Hausner in 1947 (Ref 48), followed closely by P. Schwarzkopf (Ref 49). Two years later, the first of four volumes of a treatise on powder metallurgy, a major work by C.G. Goetzel (Ref 50), was published. Some current "Selected References" on powder metallurgy science and technology are listed at the end of this article.

Powder Metallurgy Trade Associations

The advancement of powder metallurgy from a laboratory curiosity to an industrial technology has been influenced greatly by various professional societies and the P/M trade association, whose annual technical conference proceedings chronicle the maturing of the technology. In 1944, an organization called the Metal Powder Association was founded by a

group of metal powder producers in the United States. It was reorganized in 1958 as the Metal Powder Industries Federation, a trade association whose representation embraced the commercial and technological interests of the total metal powder producing and consuming industries. International in scope, the Federation consists of the following autonomous associations, which together represent the primary elements of the P/M and particulate materials industries:

- *Powder Metallurgy Parts Association*: Members are companies that manufacture P/M parts for sale on the open market.
- *Metal Powder Producers Association*: Members are producers of metal powders in any form for any use.
- *Powder Metallurgy Equipment Association*: Members are manufacturers of P/M processing equipment and supplies, including compacting presses, sintering furnaces, belts, tools and dies, and atmospheres.
- *Refractory Metals Association*: Members are manufacturers of powders or products from tungsten, molybdenum, tantalum, niobium, and cobalt.
- *Advanced Particulate Materials Association (APMA)*: Members are companies that use P/M or other related processes to produce any of a wide variety of materials not covered by the other MPIF associations as well as companies that have proprietary P/M parts manufacturing facilities. It also includes emerging technologies that use the powders as precursors in manufacturing processes.
- *Metal Injection Molding Association (MIMA)*: Members are international companies that use the metal or ceramic injection molding process to form parts.

MPIF also has both Overseas and Affiliate/Consultant classes of membership.

The Federation generates industry statistics, process and materials standards, industrial public relations and market development, government programs, research, and various educational programs and materials.

The technology's "professional" society is APMI International. As distinguished from the Federation, APMI members are individuals, not companies. Members are kept informed of developments in P/M technology through local section activities, conferences, and publications, including the *International Journal of Powder Metallurgy and Powder Technology*. It is the only professional society organized specifically to serve the powder metallurgist and the P/M industry.

Many of the major professional societies are also active in powder metallurgy, usually through committees working on standards, conferences, or publications. This includes the ASM International, the Metallurgical Society, SAE, the American Society for Testing and Materials, and the Society of Manufacturing Engineers.

Introduction

THE POWDER METALLURGY (P/M) process is a near-net or net-shape manufacturing process that combines the features of shape-making technology for powder compaction with the development of final material and design properties (physical and mechanical) during subsequent densification or consolidation processes (e.g., sintering). It is critical to recognize this interrelationship at the outset of the design process because a subtle change in the manufacturing process can cause a significant change in material properties.

General P/M Design Considerations

To begin a design using powder processing, six key design considerations must be recognized. With the variety of powder processing schemes available, the selection of the appropriate method depends to a great extent on these design constraints.

Size. Due to the physical nature of the processes and the physical limits of commercial manufacturing equipment, product size has certain critical boundaries. For some powder processes, the product size is quite limited (such as metal injection molding, MIM), while for hot-isostatic pressing (HIP), size is not considered a serious constraint.

Shape Complexity. Powder metallurgy is a flexible process capable of producing complex shapes. The ability to develop complex shapes in powder processing is determined by the method used to consolidate the powders. Because a die or mold provides the container for the consolidation step, the ease of manufacture of the container and the ability to remove a green compact (unsintered) from the container, in most cases, determines the allowable shape complexity of a given part.

Tolerances. Control of dimensional tolerances, a demanding feature of all near-net or net-shape manufacturing processes, is a complex issue in powder processing. Tolerances are determined by such process parameters as powder characteristics, compaction parameters, and the sinter cycle. The amount of densification during sintering and the uniformity of that shrinkage controls dimensional tolerance in most P/M products. Due to the very small amount of size change during sintering of conventional press-and-sinter P/M parts, these products typically have the closest dimensional tolerances, as compared to HIP parts, which require the largest spread in tolerances.

Material Systems. Powder shape, size, and purity are important factors in the application of a powder processing technique. For some consolidation processes or steps, powders must be smooth, spherical particles, but for other processes a much more irregular powder shape is required. Nearly every material and alloy system is available in powder form. For some materials such as cemented carbides, copper-tungsten composites and the refractory metals (tungsten, molybdenum, tantalum, etc.), powder processing is the only commercially viable manufacturing process.

As an example, for "press and sinter" processing, an irregular powder shape and distribution of particle sizes are desired for adequate green strength and sinter response. Hot isostatic pressing requires spherical powders (gas atomized) for lowest impurities and good particle packing. The MIM process also prefers spherical particles, but very small particle size (10 to 20 μm) is needed to ensure proper rheology, homogeneous distribution in the plastic binder, and excellent sinter response.

Properties. The functional response of any product is determined by its physical or mechanical properties. In powder processing these properties are influenced directly by the product density, the raw material (powder), and the processing conditions (most often the sintering cycle). As P/M materials deviate from full density, the properties decrease (as shown for the tensile properties--and electrical conductivity--of pure copper in Fig. 1). The mechanical response for 4% Ni steels is found in Fig. 2.

Fig. 1 Properties of pure copper. Source: Ref 1

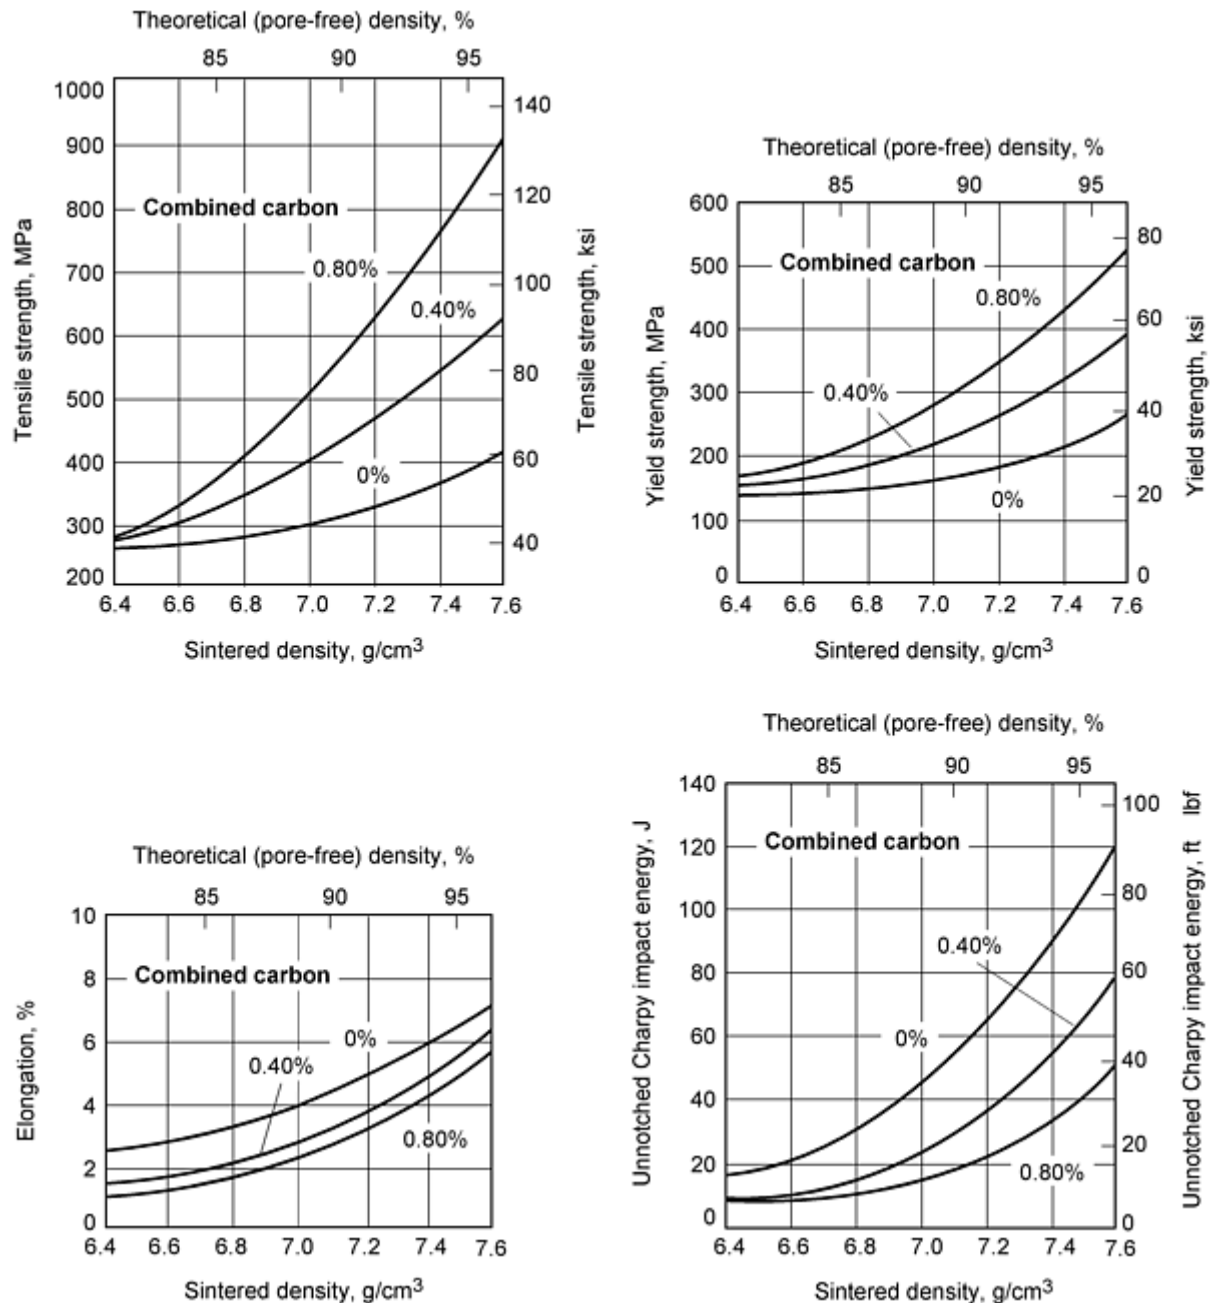

Fig. 2 Effects of density on mechanical properties of as-sintered 4% Ni steel. Source: Ref 2

Quantity and Cost. The economic feasibility of P/M processing is typically a function of the number of pieces being produced. For conventional press-and-sinter processing, production quantities of at least 1,000 to 10,000 pieces are desired in order to amortize the tooling investment. In contrast, isostatic processing can be feasible for much lower quantities, in some cases as small as 1 to 10 pieces. On a per pound basis, the approximate costs for steel P/M parts produced by various methods are roughly as follows:

Condition	Density range, g/cm ³	1997 selling price ^(a) , \$/lb
Pressed and sintered	6.0-7.1	2.45-2.70
Pressed, sintered, sized	6.0-7.1	2.90-3.20
Copper infiltrated	7.3-7.5	3.50-3.55
Warm formed	7.2-7.4	3.10-3.30
Double pressed and sintered	7.2-7.4	4.00-4.10
Metal injection molded	7.5-7.6	45.0-70.0
Hot forged	7.8	5.00-5.50
Double press and sinter + HIP	7.87	6.00-7.00

(a) These numbers are only averages; smaller parts are more expensive and larger parts less expensive per pound.

Powder Processing Techniques

In order to understand the design restrictions of each powder processing method, it is best to review these processes individually. The P/M manufacturing methods can be divided into two main categories: conventional press-and-sinter methods and full-density processes.

Conventional (Press-and-Sinter) Processes. The conventional press-and-sinter process technologies follow the steps outlined in Fig. 3. The various powder ingredients are selected to satisfy the process constraints and still meet the requirements of the end product. For example, in cold compaction irregularly shaped powders are used to ensure adequate green strength and structural integrity of the as-pressed product. Special solid lubricants are added to the powder blend to reduce friction between the powder particles and the tooling. If these lubricants might contaminate the metal powder particles, then an alternate consolidation method would be needed.

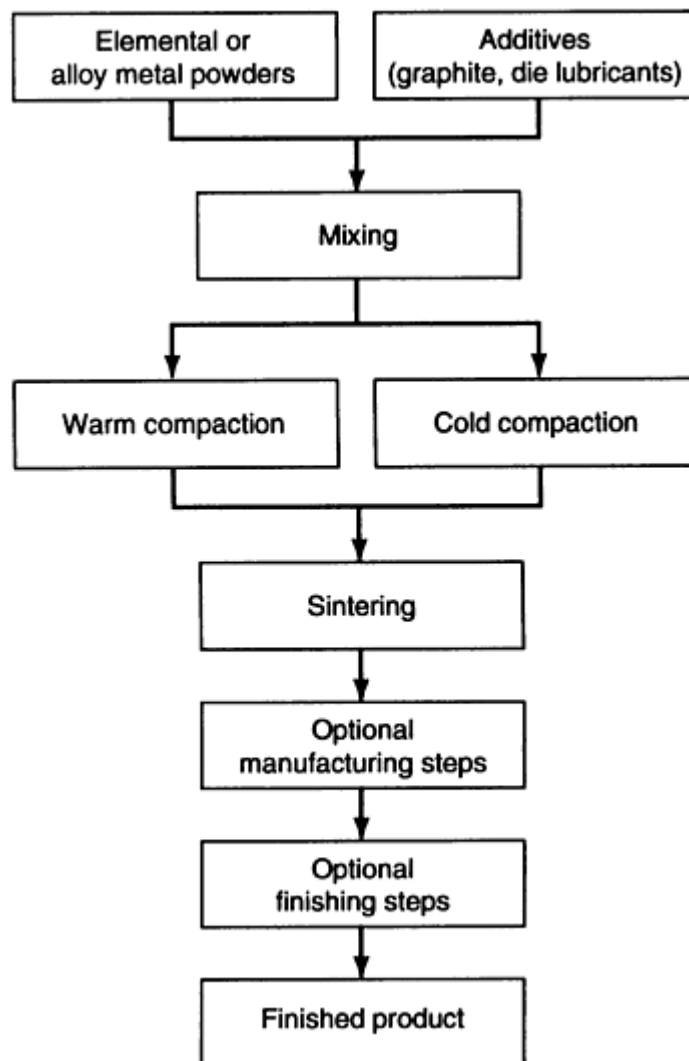

Fig. 3 General steps in the P/M process

Because powder is compacted in hard tooling using a vertical compaction motion, the product size and shape are limited by the constraints of available press capacity, powder compressibility, and the density level required in the product. For most conventional P/M products these limitations have a maximum size of about 160 cm^2 (25 in.^2) compaction area, part thickness of about 75 mm (3 in.), and a weight of 2.2 kg (5 lb). However, parts as large as 200 mm (8 in.) diameter by 100 mm (4 in.) thick, weighing 14.5 kg (32 lb), have been produced on conventional equipment. Even parts 380 mm (15 in.) in diameter by 6 mm ($\frac{1}{4}$ in.) thick have been produced by conventional P/M methods.

After compaction the green compact is sintered in a controlled-atmosphere furnace. Dimensional tolerance control is determined by the maximum temperature of the sintering cycle and the metallurgical changes that occur during sintering. If solid-state diffusion is the primary sintering mechanism, very little densification occurs, dimensional change is minimal, and tolerance control is very good. This practice is followed for most P/M steels where size change during sintering is held to less than 0.3%. In contrast, other alloy systems utilize liquid-phase formation as the primary sintering mechanism, causing a significant increase in density, large dimensional changes, and much lower tolerance control. Examples of these material systems include cemented carbides where dimensional changes of 6 to 8% are typical and tolerance control is in the range of $\pm 0.25 \text{ mm}$ ($\pm 0.010 \text{ in.}$). In addition to its effects on dimensional tolerance levels, the sintering step also plays a significant role in determining the final physical and mechanical properties of the product. Higher sintering temperatures and longer sintering times promote pore rounding and increase densification, thereby improving critical mechanical properties such as tensile strength, ductility, impact resistance, and fatigue limit (see Table 1). The sintering process is extremely important in determining the magnetic response of soft magnetic P/M alloys. As shown in Table 2 for the Fe-0.45 wt% P alloy, increasing the hydrogen content in the sintering atmosphere and raising the

sintering temperature improved the maximum permeability more than 100%, the tensile strength more than 15%, and the ductility more than 300%. In a similar manner, the mechanical properties and corrosion resistance of P/M stainless steels are strongly dependent on the sintering process parameters (Ref 5).

(a) Balance N₂.

Warm compaction is used to increase the green density and green strength of P/M steel parts. When combined with high-temperature sintering, this process can provide mechanical properties equivalent to double press-double sinter processing at a lower cost. Due to the much higher green strength, warm compacted parts can be machined in the green condition. This technique can also be used to produce insulated magnetic cores, a composite material suitable for high-frequency electromagnetic systems.

Full-Density Processes. The second group of powder process technologies are formulated specifically to yield a product as close to full density as possible. This contrasts significantly with the previous conventionally processed products where attainment of full density was not the primary goal. The full-density processes include powder forging (P/F), metal injection molding (MIM), hot isostatic pressing (HIP), roll compaction, hot pressing and extrusion.

Powder Forging. In P/F a preform is manufactured using conventional P/M process techniques and then hot formed in confined dies to cause sufficient material deformation so that nearly all the porosity is eliminated. Due to the high costs in developing the preform design and maintaining forging tools and automated production systems of the P/F process, it has been limited, in most commercial practices, to high-volume products such as automotive connecting rods and transmission components. The P/F process has been successful in developing mechanical properties in P/F steel comparable to wrought steels (see Table 3). This process successfully overcomes the mechanical property limitations imposed by the residual porosity in conventional P/M products.

Table 3 Properties of powder forged steels

Alloy	Hardness, HRC	Tensile strength		Yield strength		Elongation, %	Impact toughness	
		MPa	ksi	MPa	ksi		J	ft · lbf

Source: Ref 6

Metal Injection Molding. The MIM process combines the structural benefits of metallic materials with the shape complexity of plastic injection molding technology. A uniform mixture of powder and binders is prepared and injected into a mold (see Fig. 4). The MIM powders are typically spherical in shape and much finer in particle size than those used for conventional cold-die compaction (MIM powder, 10 to 20 μm ; conventional die-compaction powders, 50 to 150 μm). The binders are formulated specially to provide the proper rheological properties during injection molding as well as ease of binder removal after the molding step. Once the part is ejected from the mold, the binder material is removed using either solvent extraction or thermal processes (or both). After the debinding step the part is then sintered to complete the process. Due to the large amount of binder in the MIM starting material (up to 40% by volume), the MIM part undergoes a large reduction in size (as much as 20% linear shrinkage) during sintering. Dimensional tolerances, therefore, are not as good as in conventional die compaction and a straightening or coining step is sometimes needed.

Fig. 4 Metal injection molding process. Source: Ref 7

Hot Isostatic Pressing. This fully dense process method is the least constrained technique. However, due to its very low production rate, costly equipment, and unique tool requirements, the HIP process is normally relegated to expensive materials such as tool steels, superalloys, titanium, and so forth. The process also requires high-purity powders (generally spherical in shape), and it is considered only a near-net-shape process. The powders are vibrated in place in a container, which is then evacuated and sealed. These metal or ceramic containers are placed in the HIP vessel, which applies an isostatic pressure (using a gaseous medium) and temperature to the container and the powder mass. This combination of heat and pressure on the container consolidates the powder to its final shape, as defined by the initial container configuration. The container must be removed from the HIP part after the process cycle, typically by machining or chemical etching.

Other Full-Density Methods. The remaining full-density consolidation methods are used infrequently in commercial practice and are limited to specialty materials. For example, roll compaction is used to form certain soft magnetic alloys, composite materials, and compositions unique to powder metallurgy. Hot pressing is used when the deformation

characteristics of the base powder require high temperatures to achieve plastic flow and adequate consolidation. The powder extrusion process requires a container, and it is similar to roll compaction and limited to specialty materials not suitable for conventional extrusion methods, such as composites, titanium, and nuclear materials.

Comparison of Powder Processing Methods

Effective application of powder processing methods requires a general comparison of the major design features, focusing on the similarities, differences, advantages, and disadvantages of each method. Table 4 provides a qualitative comparison, while Table 5 offers more specific design information. Characteristics for each processing method are summarized below.

Conventional die compaction:

- Widest range of most frequently used engineering materials, including iron, steel, stainless steel, brass, bronze, copper, and aluminum
- Most applicable to medium-to-high production volumes; small- to medium-size parts such as gears, sprockets, pulleys, cams, levers, and pressure plates (automotive, appliances, power tools, sporting equipment, office machines, and garden tractors are typical markets)
- Greatest density range, including high-porosity filters, self-lubricating bearings, and high-performance structural parts
- Limited physical and mechanical properties caused by residual porosity
- Most cost-competitive of the powder processes
- Wide range of applications from low- to high-stress applications

Powder forging:

- Potentially applicable to all engineering materials now hot forged, but actual applications currently limited to low-alloy steels
- Product applications limited to high-volume products such as automotive connecting rods and transmission components as well as power tool parts
- Mechanical properties equivalent to wrought steel
- Most cost-competitive of the full-density processes for medium-to-large parts

Metal injection molding:

- Limited range of materials, though most standard engineering alloys available as well as several specialty alloys
- Limited to relatively small, highly complex shaped products for medium-to-high production volumes
- Greatest range in shape complexity including high aspect ratios
- More costly than conventional die-compaction processes
- Superior physical and mechanical properties as compared to conventional process, due to higher density

Hot isostatic pressing:

- Materials limited only by the inherent cost of the process, therefore typically applied only to expensive materials
- Most suited for low-to-medium production volumes
- Competitive against large casting or forging products where substantial machining is needed to obtain the final product
- Much shape detail is machined after HIP processing; not normally a "net-shape" manufacturing process
- Physical and mechanical properties meet or exceed those of cast or wrought materials

Table 4 Comparison of powder processing methods

Characteristic	Conventional	MIM	HIP	P/F
Size	Good	Fair	Excellent	Good
Shape complexity	Good	Excellent	Very good	Good
Density	Fair	Very good	Excellent	Excellent
Dimensional tolerance	Excellent	Good	Poor	Very good
Production rate	Excellent	Good	Poor	Excellent
Cost	Excellent	Good	Poor	Very good

Conventional Die Compaction

In order to use die-compaction technology effectively, the designer must be familiar with the limitations and design constraints related to product shape and special features. A shape or feature can be die compacted provided that (a) it can be ejected from the tooling and (b) the tools that form the feature have sufficient strength to withstand the repeated compaction loads. Due to the vertical closure of the tooling and the lack of tool motions perpendicular to the pressing direction, part removal from the tools controls many features. Examples of features that cannot be accommodated in die compaction, and therefore require secondary machining operations, include undercuts, reverse taper (larger on bottom than on top), annular grooves, and threads.

The specific design issues for the powder process technologies would require an extensive discussion well beyond the limits of this article. An excellent source for additional details is the manual on P/M product design prepared by the Metal Powder Industries Federation (MPIF) trade association (Ref 8). Additional information on tooling and part design is also included in the article "Powder Metallurgy Presses and Tooling" in this Volume.

Secondary Operations

A variety of secondary manufacturing and finishing operations may be required to complete the part, to improve properties, or to calibrate dimensional tolerances. Because die-compacted parts have residual porosity that may affect the response to these secondary operations, several guidelines are provided in this section.

Repressing. Die-compacted parts can be repressed in a second tool set in order to reduce the amount of porosity or reduce dimensional variation. By increasing the part density, critical physical and mechanical properties will be improved. This secondary densification step can be performed on the entire part or just specific features, for example, gear teeth. The sizing of P/M parts for improved dimensional tolerances is widely performed, especially for the manufacture of bearings.

Impregnation and Infiltration. Several procedures are used to fill the residual porosity in conventional P/M parts. Oil impregnation adds an internal lubricant to the product, which is useful in bearing and wear applications. The part can be resin impregnated to seal the pores for pressure tightness and improved machinability or to prevent the intrusion of undesired plating chemicals. Infiltration with a lower melting metal than the base material (such as copper-infiltrated steel or copper-infiltrated tungsten) is also used to seal porosity, but most often to increase mechanical properties or create unique composite structures.

Steam treating, also known as steam oxidizing, is a low-temperature (540 °C, or 1000 °F, 1 to 2 h) heat treatment process in which P/M steel parts are exposed to superheated steam. The process can be conducted in batch, pressurized furnaces, or continuous belt furnaces. The steam reacts with the iron surface converting it to an adherent, protective blue-grey iron oxide (Fe_3O_4). Because the steam can penetrate the porosity, the oxide layer can be 0.020 to 0.050 in. deep depending on the processing conditions. Steam treating enhances the product by:

- Increasing wear resistance
- Increasing surface hardness
- Improving corrosion resistance
- Increasing compressive yield strength
- Providing low-pressure leak tightness

Formation of this oxide layer unfortunately reduces tensile strength and ductility ~ 10 to 20%, depending on the material system and processing conditions.

Heat Treatment. Due to the presence of residual porosity in die-compacted P/M parts, heat-treat practices should utilize gaseous or noncorrosive liquid media (such as quench oil rather than water or fused salts). In addition, because the porosity allows for the penetration of gaseous media (i.e., carburizing gas), special steps must be considered when trying to develop a carburized case in P/M steels. The surface (or entire part) must be high enough in density to prevent the carburizing gas from penetrating the pore network. A density of 7.2 g/cm^3 or greater is desired. Copper infiltration can also be used to seal the part for a case-carburizing treatment. Heat treatment of P/M steels is most effective in improving mechanical properties when parts have a density greater than 7.0 g/cm^3 .

Finishing. The variety of finishing operations--machining, plating, deburring, joining--must also consider the effects of residual porosity. Improvements in machinability have been achieved through resin impregnation (seals the porosity) and by adding machinability aids to the original powder blend. Surface finishing may also require resin impregnation if the part density is low enough to allow entrapment of plating or finishing chemicals. These liquids can cause internal corrosion of the P/M part if allowed to penetrate the open porosity network. For welding and brazing, precautions are necessary to ensure a sound joint (Ref 8).

Material Selection

Once the die-compaction processing method has been selected the designer must consider the product configuration and material requirements. Previous sections have discussed the design constraints regarding shape and configuration. The next step in the procedure (see Fig. 5) is comparing the critical part performance requirements with the available P/M materials. Reference 5 serves as a very useful source of material property data. In many cases, more than one material can satisfy the design performance requirements. Therefore, the various production methods must be considered because these affect the ultimate cost of the product.

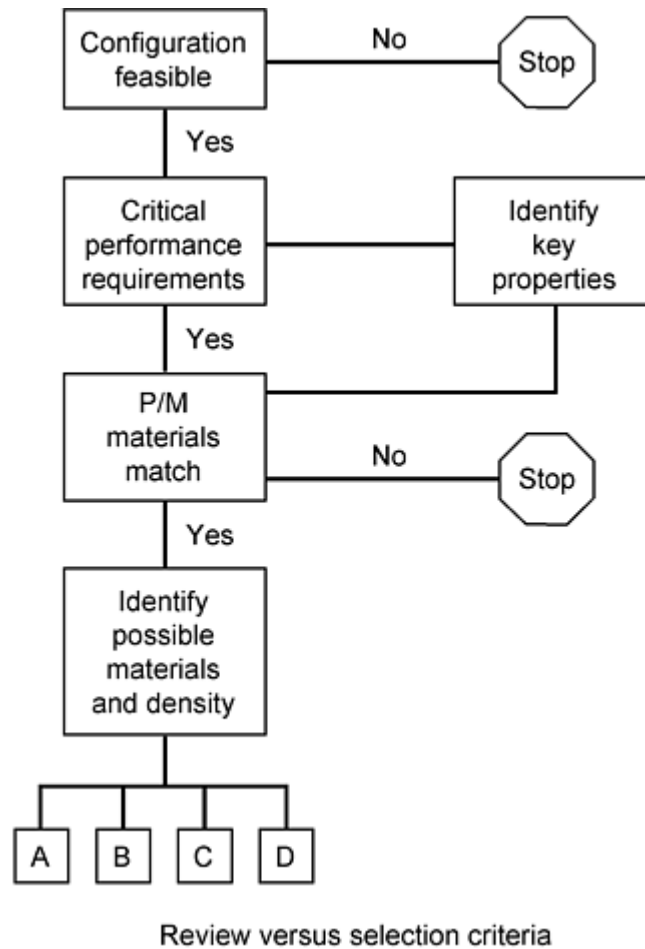

Fig. 5 Material selection method

Figure 6 provides the second evaluation scheme. Starting from the material selected, this leads directly to the density needed in the critical section of the part. Knowing the desired density leads to a preliminary selection of the powder and press size necessary to reach the required density. From this point the remainder of the processing steps are considered. For example, is a conventional sintering process or a "high-temperature" process needed? Will a repressing-resintering process be necessary to achieve the density selected? What secondary processing treatments are needed, and how will the density affect these processes? Using a standard press-and-sinter process as a baseline, the cost of high-temperature sintering may add a 10 to 20% premium, while a double-press/double-sinter process could result in as much as a 40% premium (Fig. 7). Therefore, the designer must recognize that selecting a material and density level leads directly to a processing cycle and the cost associated with the process. A judicious review and selection of materials can ensure the most cost-effective product design.

Bearings

Due to the unique self-lubricating characteristics of P/M bearings, these products have additional design guidelines. After conventional die compaction and sintering, bearings are vacuum-oil impregnated to fill the interconnected porosity with oil. The design of P/M bearings and selection of the optimal alloy depend primarily on shaft velocity and bearing load. Other design factors include type of operation (stop-start versus continuous), shaft surface finish, type of lubricant, and conditions of uneven loading. The MPIF bearing standard (Ref 9) provides a systematic guide for these design issues:

- Recommended load as a function of shaft velocity
- Environmental factors that can reduce permissible loads
- Recommended press fits
- Running clearances
- Dimensional tolerances

The selection of a bearing alloy normally considers the following factors:

- Chemical compatibility with the lubricant
- Thermal conductivity to dissipate heat
- Mechanical properties to maintain structural integrity and withstand press-fit installation forces
- Antigalling with the shaft material
- Wear characteristics with the shaft material

Six commercial alloys dominate the self-lubricating bearing designs: bronze, diluted bronze, plain carbon steel, iron-copper alloys, copper steels, and iron-graphite. Graphite can be used as a solid lubricant and is added to the powder mix prior to compacting. More information on these materials can be found in Ref 9 and the article "Powder Metallurgy Bearings" in this Volume.

In some products the designer can incorporate bearing surfaces into the part, thereby eliminating the need for separately fabricated and installed bearings. The following design restrictions must be followed:

- Bearing areas should have a minimum of 10% interconnected porosity to provide sufficient oil capacity.
- Infiltration is not allowed in the bearing areas because the infiltration will fill the open pores.
- Machining on the bearing surfaces must be performed to avoid sealing or closing off the open porosity.

Metal Injection Molding

The MIM process is similar to plastic injection molding: (1) material is fed into the mold cavity through gates, which may leave a visible mark on the part; (2) the mold must open, leaving a parting line on the part; and (3) the part must be ejected from the mold cavity using ejector pins, which also may leave visible marks on the part. Location of the parting line is critical to the orientation of part features. To the extent possible, all features should be oriented perpendicular to the plane of the parting line to facilitate removing the part from the mold. Features not so oriented require additional tooling, such as side pulls.

The optimal location of gates is a design balance between product and processing requirements. In general, gates are located on the parting line, positioned to direct flow onto a core rod or cavity wall. Where wall thicknesses vary, gates are located so the material flows from thicker sections to thinner sections. Ejector pins push the molded part off of the mold cores. There must be enough pins to free the part off of the core without damaging or distorting the as-molded part. Typically, these pins are located near features requiring the highest ejection forces, such as cored holes. Because the pins leave permanent marks, they should be positioned on recessed features, surfaces that will be machined, or unused areas such as runners.

Injection-molded parts are normally placed on flat plates or shelves for thermal debinding and sintering. A geometric feature that allows the part to rest securely with no additional support is preferred. Long spans, cantilevers, or delicate resting points may require special fixtures or setters to minimize distortion during sintering. A postsintering straightening operation may also be required.

Shape and Features. The design features that can be produced by MIM are similar to those made by conventional plastic injection molding or die casting. Dimensions and proportions are different due to the small size of MIM parts and molding characteristics of the MIM materials.

To facilitate release and ejection of the molded part, draft is normally in the range of $\frac{1}{2}^\circ$ to 2° . Draft should be uniform on all features of the part to facilitate mold fabrication and be near the upper range with more complex part features or multiple cores.

Where feasible, walls should be of uniform thickness throughout the part (Fig. 8). Variations in thickness can lead to distortion, internal stresses, voids, cracking, and sink marks. In addition, thickness variations cause nonuniform shrinkage during sintering, leading to greater size variation and looser tolerances. A thickness in the range of 1.25 to 6.35 mm (0.050 to 0.250 in.) is preferred. Common ways of modifying a part to make wall thickness more uniform or ease the transition from thick to thin are shown in Fig. 9. More detailed design tips are found in Ref 8.

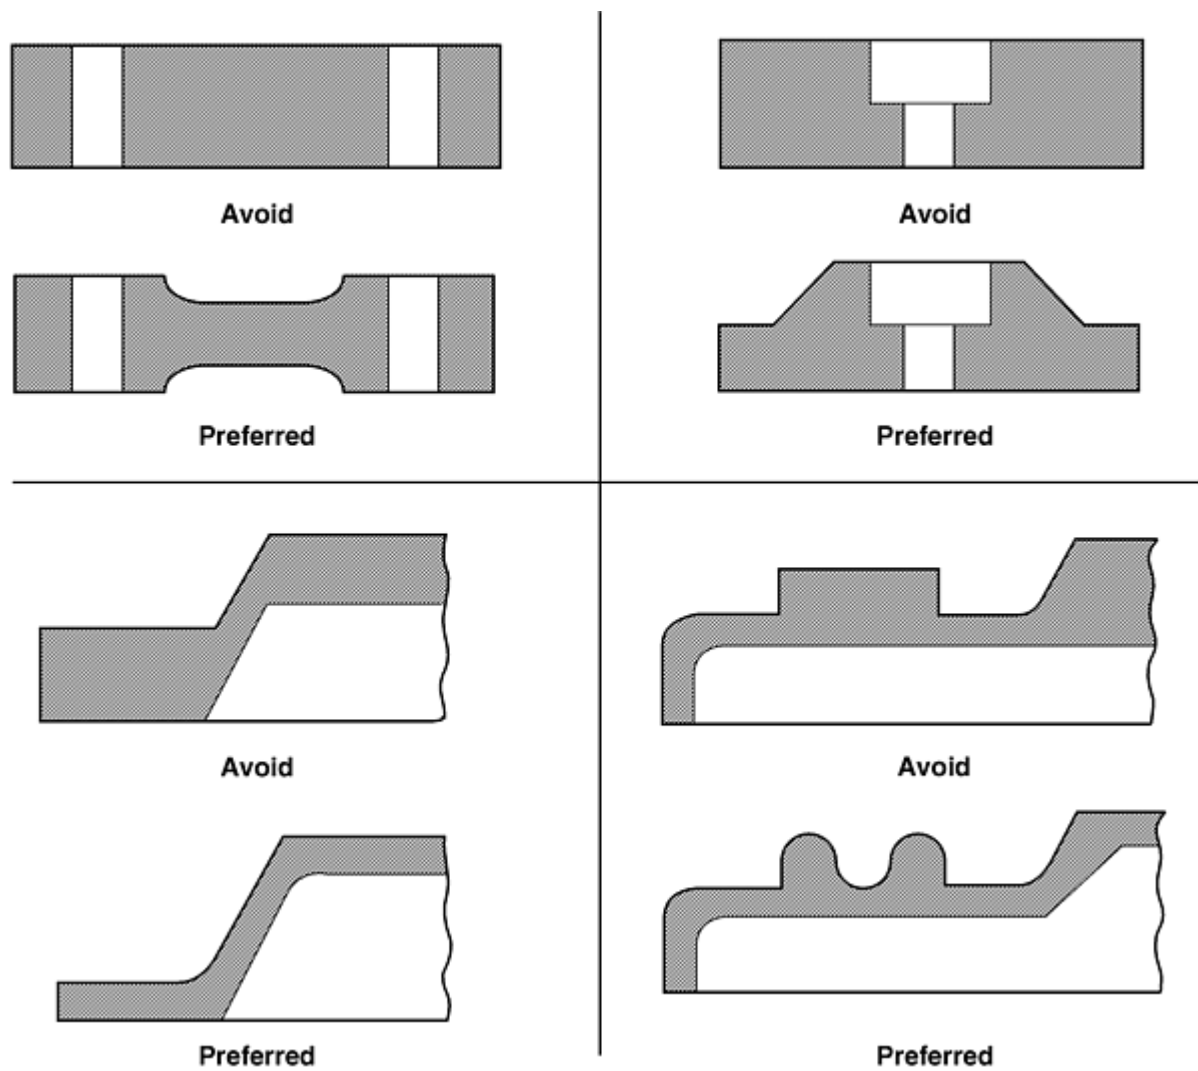

Fig. 8 Designs for maintaining uniform wall thickness in MIM parts. Source: Ref 8

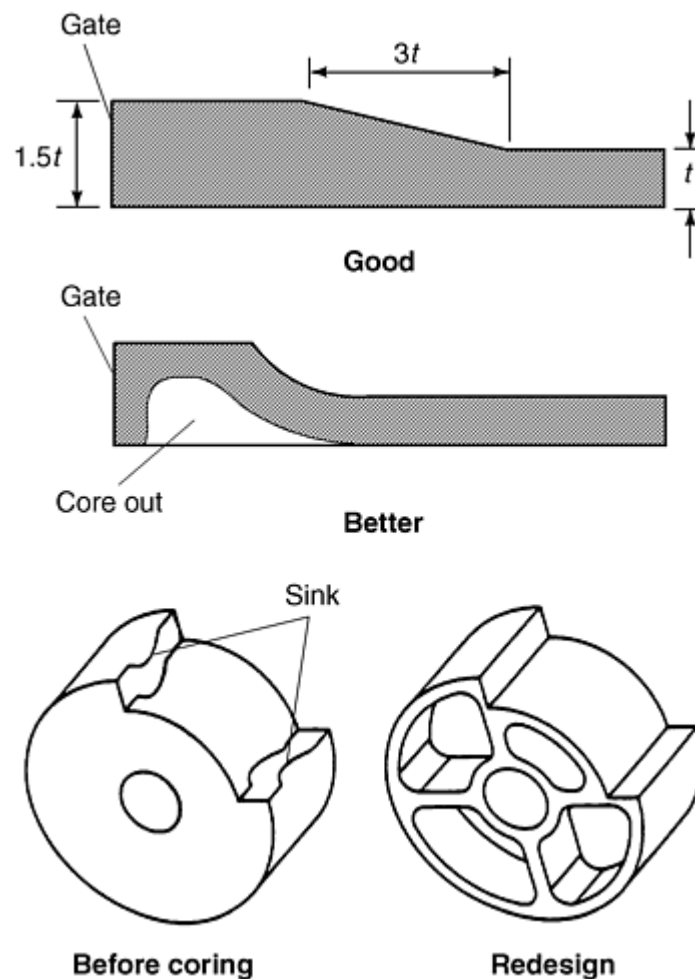

Fig. 9 Redesign of a MIM part to establish uniform wall thickness. Source: Ref 8

Material Selection. The material systems currently in commercial use include ferrous alloys (low-alloy steel, stainless steels, soft magnetic alloys), nonferrous alloys (brass, bronze), tungsten carbide, pure nickel, electronic alloys (Invar, Kovar), and tungsten-copper composites. The physical and mechanical properties of several MIM engineering alloys (low-alloy steel and stainless steels) have been standardized by MPIF (Ref 10). After sintering, the residual porosity in MIM parts is very low and not interconnected. With densities typically in excess of 96% of theoretical density, the resultant mechanical properties are superior to conventional die-compacted P/M materials and more closely match the properties of investment castings in similar alloys. Therefore, the limitations discussed previously regarding the residual porosity in conventional die-compacted products do not apply to MIM parts. Secondary operations can be performed with no restrictions.

Powder Forging

The design issues in P/F are similar to the requirement of any precision, closed-die forging. The difference is the starting preform; in the case of P/F, the preform is a sintered powder metal part, typically 80 to 85% of theoretical density, with a shape similar to the final part configuration. By contrast, in a precision closed-die forging the preform is a wrought steel blank with very little shape detail. Preform design for P/F fabrication determines the extent of product shape detail required to meet the performance requirements of the finished P/F part. Preform design is a complex, iterative process currently modeled by computer simulation software programs to help reduce design time and development costs.

In the forging step, the P/M preform is removed from the reheat (or sintering) furnace, coated with a die lube, and forged in a heated, closed die operation. The forging process reduces the preform height and forces metal into the recesses of the closed die. This step also brings all features to their final tolerances and densities.

Configuration guidelines, typical of precision closed-die forged parts, also apply to P/F parts as follows:

- Radii on inside corners of the forging as large as possible to promote metal flow around corners in the tool and promote complete fill of all details.
- Radii of at least 1 mm (0.040 in.) on all outside corners of the forging to aid in material flow to define features.
- Shape of the forging should be such that, when placed in the die, the lateral forces will be balanced. Shapes that are symmetrical along a vertical plane, such as connecting rods and shapes that are axisymmetric (or nearly so), are preferred.
- Zero draft is possible on surfaces formed by the die and core rod, but not by the upper punch.
- Re-entrant angles (undercuts) cannot be forged.
- Axial tolerances--in the direction of forging--are driven by variations in the mass of metal in the preform. Lateral tolerances are driven by metal flow as the cavity fills. Typical axial tolerance of 0.25 to 0.5 mm (0.010 to 0.020 in.) are encountered, with diametric tolerances of 0.003 to 0.005 mm/mm of diameter.
- Concentricity of a P/F part is determined by the quality and density distribution in the preform. Concentricity is normally double that of the preform.

Introduction

POWDER METALLURGY parts can be broadly separated into three categories: those in which the P/M approach allows a lower-cost component to be produced, an intermediate category of cost-effective/high-performance parts, and those in which the P/M approach leads to a part with enhanced mechanical property characteristics (Ref 1, 2, 3). The first approach generally results in a product with lower mechanical properties than wrought product, the third is normally a higher-cost approach. The low-cost P/M product is the more traditional commercial approach, the second has been more recently established commercially, and high-performance parts represent a developing facet of P/M technology.

Many P/M parts are now used in a variety of industries, including automobiles, household appliances, yard and garden equipment, computers, fabric industry equipment, and orthodontic devices (Ref 4). The growth in North American metal powder shipments up to 1996 is shown in Table 1 (Ref 5).

Table 1 North American metal powder shipments

	Shipments, tons				
	1992	1993	1994	1995	1996
Iron and steel	246,300	287,550	337,850	347,172	350,603
Copper and copper base	20,000	22,400	23,100	23,216	22,891
Aluminum	29,700	29,500	43,700	37,044	34,179
Molybdenum	2,500(E)	2,500(E)	2,500(E)	2,500(E)	2,500(E)
Tungsten	1,450	1,900	1,450	1,445	1,000(E)
Tungsten carbide	4,500	5,200	6,200	10,846	11,200(E)

Nickel	9,900	9,600	10,000	10,476	11,600(E)
Tin	950	1,100	1,250	1,010	1,010
Total	315,300	359,750	426,050	433,709	434,983

Source: Ref 5

(a) E, estimate.

In 1995, North American powder metal shipments totaled 437,774 tons, a 2% increase from the previous year. Iron and steel powder shipments amounted to 347,172 tons, up 2.7% from 1994. Parts applications for iron/steel powders accounted for a record-high 312,974 tons, an increase of 3.1%. However, it was the first time in four years that the parts market improved by a percentage of less than double digits. In the 1992 to 1994 period, the parts market for North American iron and steel powder producers, the biggest market of its kind in the world, grew at an average annual rate of 18.6%.

Automotive parts continue to be the leading application of P/M parts. The typical U.S. automobile contains about 14 kg (30 lb) of P/M parts with an increase expected in the next several years (Fig. 1). A slightly lower amount is used in Japanese automobiles (Table 2) (Ref 6), but automotive application of P/M parts is still the dominant use in Japan as well (Fig. 2). The growth of P/M parts in automobiles is due to increased use of P/M components in engines, transmissions, brakes, airbags, and other complex parts. Emerging automotive applications are also described at the end of this article.

Table 2 Average weight of P/M components used in each Japanese car

Year	Cars, $\times 10^3$	P/M part, t	Weight	
			kg/car	lb/car
1980	11,175	33,923	3.03	6.68
1987	12,350	52,921	4.29	9.46
1988	12,819	60,046	4.68	10.3
1989	12,953	70,138	5.41	11.9
1990	13,592	75,459	5.55	12.2
1991	13,145	75,099	5.71	12.6

Net Shape Capability

A major advantage of the P/M approach is the net-shape capability, particularly for high-strength materials. This has led to continuing developments in P/M technologies for parts production.

Warm Compaction. One recent development in P/M production is warm compaction, which allows the production of higher-density ferrous P/M parts via a single compaction process. The process utilizes heated tooling and powder during the compaction step. The powder and tooling are typically heated between 130 and 150 °C (260 and 300 °F). In order for the powder premix to perform at these temperatures, a proprietary lubricant system has been developed that provides lower die ejection forces than conventional lubricants. This lubricant system also incorporates a polymeric binder system to limit segregation and provide enhanced flow characteristics of the powder premix. By utilizing warm compaction technology, the green density of the consolidated part can be increased from 0.10 to 0.25 g/cm³ over traditionally processed (single-pressed/single-sintered) materials. The green strength is typically increased between 50 and 100%.

Table 3 (Ref 7) compares the green properties of warm-compacted and cold-compacted P/M parts. This increase in green strength provides advantages such as a reduction in green chipping and cracking due to part handling prior to sintering and makes possible the crack-free compaction of complex multilevel parts. Additionally, the higher green strength provides an opportunity to machine the P/M part in the green state. This capability is critical in the use of high-performance alloy systems that achieve high hardness in the as-sintered state. Warm compaction also enables P/M fabricators to single press and single sinter ferrous P/M parts to densities as high as approximately 7.4 g/cm³, which is considerably higher than cold-compacted-and-sintered P/M parts.

Table 3 Effect of processing on the green properties of ferrous compacts

Base material	Processing technique	Compaction pressure		Green density, g/cm ³	Green strength		Peak die ejection force	
		MPa	tsi		MPa	psi	MPa	tsi
Acorsteel 85HP ^(a)	Warm compaction	415	30	7.14	23.2	3370	29.6	2.15
		550	40	7.31	25.4	3685	33.5	2.43

		700	50	7.37	24.7	3580	32.0	2.32
	Cold compaction	415	30	7.00	9.9	1430	37.2	2.70
		550	40	7.19	12.2	1770	50.7	3.68
		700	50	7.29	13.4	1950	53.8	3.90
Distaloy 4800A^(b)	Warm compaction	415	30	7.07	28.3	4100	27.4	1.99
		550	40	7.29	30.6	4445	31.7	2.30
		700	50	7.36	31.1	4515	32.3	2.37
	Cold compaction	415	30	6.93	12.2	1770	37.2	2.70
		550	40	7.15	15.0	2170	48.5	3.52
		700	50	7.26	16.9	2450	52.0	3.77

Source: Ref 7

(a) Ancorsteel 85HP is a prealloyed steel powder containing 2.0% Ni, 0.85% Mo, 0.4% graphite, and 0.6% lubricant.

(b) Distaloy 4800A is a diffusion-alloyed steel powder containing 4% Ni, 1.5% Cu, 0.50% Mo, 0.5% graphite, and 0.6% lubricant.

Warm compaction, although applicable to all ferrous material systems, produces the greatest benefits when coupled with high-performance compositions such as diffusion-alloyed steels or molybdenum-prealloyed steels. Achieving densities in excess of 7.25 g/cm^3 using these compositions results in mechanical properties that are comparable to steel forgings and ductile iron castings.

Stainless Steels. Other developments in conventional P/M steels include new and improved stainless steels, with the goal of improving compressibility and corrosion resistance. Developing applications include automobile parts such as a solenoid spacer in an electronic fuel injector, sealing washers in the water pump, and brake components. They also include other applications such as bearing holders and pulleys in computers.

Metal injection molding (MIM), which is finding increased use in small parts manufacturing, uses fine powders (5-10 μm) that exhibit good sintering densification in combination with binders that hold the particles in place for transportation (Ref 8). The basic five steps involved are feedstock characterization, mixing rheology, injection molding, debinding, and sintering (see Fig. 4 in the article "Powder Metallurgy Methods and Design" in this Volume). With tolerances as low as 0.3%, sizing is generally not required. Densification to a usable article is accomplished in the sintering furnace. However, surrounding these seemingly simple steps there is a great deal of "know-how" that has been developed.

Metal injection molding occupies a certain region in the part-size/production-run/part-complexity scenario (Fig. 3). Sizes are generally in the 1 to 200 g range, but parts as large as 1 kg have been made by MIM. The near-net-shape capabilities

of the process can reduce machining costs to low levels, especially for long runs ($\geq 10,000$ parts). For small complex components, cost savings can be up to 80% compared to conventional approaches. A wide range of geometric options are possible including undercuts, tapered external surfaces, and crossholes. Short production runs can be cost effective, but because of die and powder costs, this only occurs with very complex shapes and/or hard materials.

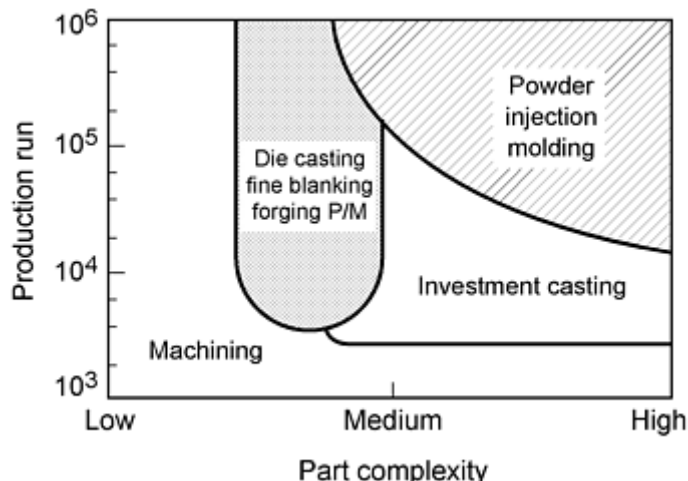

Fig. 3 Section of the part-size/production-run/part-complexity diagram where the MIM process is most effective. Source: Ref 8

Some MIM fabricators produce runs of 2000 to 5000 pieces, particularly on more expensive parts (Ref 9). They can do a short run such as these because there is no danger to the tooling at setup, while in conventional P/M there is more risk. The capital equipment (presses) for injection molding is more economical than that for large-scale P/M presses. Tool life is at least 300,000 pieces. These factors help offset the added short-term material cost.

Two of the first MIM production parts in automobiles were parts for an ignition lock (Fig. 4) and a single-part replacement (Fig. 5a) for a two-part turn signal lever assembly (Fig. 5b). Both have been in service since July 1988.

Fig. 4 MIM part (upper left) for an automobile ignition lock. The key forces the MIM part into contact with a security switch. Courtesy of SSI Technologies

Fig. 5 (a) Single-piece MIM part that replaced (b) a two-piece automobile turn signal lever assembly. The smaller MIM part in (a) was the first version, while the larger MIM part is the finished version that replaced the two-part assembly shown in (b). Courtesy Remington Arms Division of E.I. Du Pont de Nemours & Company, Inc.

Figure 4 shows the entire ignition lock and the MIM subcomponent. As the key is inserted in the lock, the cam-shaped MIM part moves away and depresses an electrical switch, which is part of the security system. The initial design of the part was too small and complicated for the model shop to make, and it was prototyped from the MIM tooling.

The turn signal indicator lever is an example of the replacement of a two-piece assembly (Fig. 5b) with a single MIM part. The lower portion of Fig. 5(a) shows the first version of the MIM part, and the upper view shows the final 19.0 g (0.670 oz) MIM part that replaced the assembly. The MIM material is iron with 2% Ni, sintered and then case hardened. It replaced AISI 4037 and SAE 1018 case hardened. The MIM part succeeded because of its superior strength compared to the two-piece assembly. The core properties of the materials are 415 MPa (60 ksi) tensile strength and 15% elongation at 60 HRB.

Hot powder forging (P/F) continues to be attractive for the production of fully dense P/M parts for demanding applications (Ref 10, 11, 12). In this process a loose powder is blended to the desired composition and pressed to a forging preform having the general shape of the final component. Powder forging has proven to be competitive when the overall economics are improved through some combination of enhanced machining characteristics, mechanical properties, and dimensional or weight tolerances.

It was initially believed that P/F products would displace a wide variety of conventionally processed P/M parts, as well as a significant number of conventional forgings. However, the number of high-volume applications has been limited to bearing races, connecting rods, and ring gears.

One of the more dramatic applications in the mid-1980s was P/F connecting rods. Compared with conventional forging, P/F technology improved weight and dimensional control (Fig. 6) and reduced machining requirements (Fig. 7). In addition, P/F connecting rods are always forged in one piece, where the rod and cap are separated by "fracture splitting." Use of this technique eliminates several machining operations. In addition, the irregular, mating fracture surfaces (ductile failure mode) provide an intimate interlock between rod and cap. This virtually eliminates both "cap shift"--rotation of the cap relative to the rod--and lateral movement of the cap relative to the rod. Cap shift can lead to accelerated wearing of surfaces and, in extreme cases, bearing seizure. Lateral movement can result in high shear stress on connecting rod bolts at high engine revolutions per minute.

Dimension	Powder forge variation ^(a) , %	Conventional forge variation ^(a) , %
A: Pin end outside diameter	0.19	2.09
B: Bolt boss width	0.11	0.28
C: Crank bore diameter	0.14	0.31
D: Pin bore diameter	0.15	^(b)
E: Bore-to-bore center distance	0.10	0.17
F: I-beam width at pin end	0.42	3.16
G: I-beam width at crank end	0.35	0.95
H: Bolt head seat location	0.06	1.11
I: Crank end thickness^(c)	0.58	1.13
J: Pin end thickness^(c)	0.45	0.48

(a) Variation evaluated as the ratio of the range of measurements to the mean dimension.

Cost-Effective, High-Performance Parts

So called "mid-range" parts are not generally considered exceptionally low in cost, but rather as parts for which a cost reduction and improved behavior can both be obtained. There are many parts in this category that are the subject of current production programs. They generally fall into three categories of parts: billet materials, P/M near-net shapes, and clad composite materials.

Billet Materials. A good example of billet materials are high-speed steel billets made by hot isostatic pressing (HIP) of gas-atomized powders. This material is current bill-of-material for about 8000 tons/year of high-speed steels

manufactured in both the United States and Europe (Ref 13). It is typically competitively priced with cast and wrought material and has a strong advantage for the larger size products due to its fine, uniform carbide size. This gives it manufacturing advantages (especially grindability) and performance advantages over conventional cast and wrought material. Other widely used P/M billet materials include sputtering targets for applying the coatings used in data storage applications. Important materials are powders such as chromium, chromium alloys, and cobalt alloys. Important characteristics are 100% density, high purity, and uniformity of chemical composition, traits that are the trademark of HIP P/M materials.

Powder metallurgy near-net shapes have made their mark for production applications in several industries. Power turbines for instance have used rotors, rings, and disks (Ref 14) HIP densified from steel alloys such as 12% Cr (X 20 CrMo V 12 1) and 9% Cr 1% Mo (Grade 91). The P/M alloys are superior to their wrought counterparts in that the properties developed are isotropic and are equivalent to the maximum wrought properties in the forging direction. Powder metallurgy near-net shape manifolds and valve bodies have become standard production items in the North Sea oil fields in alloys such as austenitic and duplex (ferritic-austenitic) stainless steels (Ref 15). Manifold sections can be made as net shapes with no machining except for the mating surfaces on connecting flanges. Individual parts are then welded into sections for use in underwater applications. Also, P/M near-net shapes are finding acceptance for pump and valve components in hostile environments.

The advantage these parts have compared to closed-die forgings is that they have the same properties as the maximum forged properties in all directions (isotropic), but with inside detail that is not possible with forgings. Also, the delivery time is much shorter for first deliveries for the P/M parts due to much more simplified tooling.

HIP cladding of powder materials on solid substrates has become an important engineering technique in a number of applications involving improving corrosion, erosion, and wear properties. The advantage of the technique is that the P/M alloy can be engineered precisely for the environmental factors and then applied in sparing quantities in such a way that a metallurgical bond is created with a low-cost substrate that will withstand the rigors of the application. A good example is tooling for plastic extrusion. Corrosion resistance can be provided, for example, by selecting a gas-atomized nickel-chromium alloy as a base and blending in tungsten carbides for wear resistance. This powder can be HIP bonded to the inside surface of relatively inexpensive steel barrels to provide a duplex material capable of giving long life in extruder service.

Advances in Powder Metallurgy Applications

F.H. "Sam" Froes, Institute for Materials and Advanced Processes (IMAP), University of Idaho, and John Hebeisen, Bodycote IMT, Inc.

Advanced Synthesis

Far-from-equilibrium synthesis leads to novel constitutional and microstructural effects and enhanced physical properties (Ref 16). A number of these techniques are summarized in the sections that follow in Table 4 with emphasis on the amount of departure from equilibrium.

Table 4 Departure from equilibrium achieved in various processes

Process	Maximum departure from equilibrium, kJ/N_a
Solid-state quench	16
Quench from liquid (rapid solidification)	24
Mechanical alloying	30
Condensation from vapor	160

(a) N_a , Avogadro's number of atoms

Rapid Solidification

Rapid solidification (RS) allows extension of solubility limits, production of novel phases, and more refined microstructures than ingot metallurgy (I/M) techniques. The greatly increased chemistry/microstructure "window" can lead to enhanced mechanical and physical properties.

Aluminum. Five families of alloys being explored using the RS approach are the high-strength corrosion-resistant alloys based on traditional 7000-series alloys, low-density aluminum-lithium alloys with increased lithium levels over those possible using the I/M approach, dispersoid-strengthened elevated-temperature alloys based on low-solubility/low-diffusion-rate additions such as the transitional metals (iron, molybdenum, nickel) and rare earth elements (cerium), wear-resistant high-silicon alloys, and recycled alloys (in which conventional ingot processing would lead to excessive segregation)(Table 5).

Table 5 Tensile properties of elevated-temperature P/M RS aluminum alloys at 315 °C (longitudinal)

Alloy	Ultimate tensile strength, MPa	Yield strength, MPa	Elongation %
Al-Fe-Ce	270	225	7
Al-Fe-Mo	235	210	10
Al-Fe-V-Si	310	300	7
Al-Zr-Cr-Mn	235	215	. . .

Magnesium. Cast magnesium alloys exhibit lower than desirable strength, ductility, and creep behavior, and the nonprotective oxide skin can lead to severe corrosion problems. High-strength, corrosion-resistant magnesium alloys containing rare earth additions (yttrium, neodymium, cerium) have been developed using RS. Mg-Al-Zn-X ($X = \text{Si, Y, Nd, or Ce}$) alloys can exhibit tensile strengths ranging between 450 and 510 MPa. These alloys have strength and ductility combinations equivalent to high-strength aluminum alloys and are five times more corrosion resistant than the most resistant conventional magnesium alloys.

Titanium. The major concentration on RS terminal alloys to date has been to enhance elevated-temperature capability beyond I/M alloy levels (i.e., $>700^{\circ}\text{C}$) through dispersion hardening (Ref 2, 3). The additions of erbium and other rare earth elements produce dispersoids that resist coarsening at least up to 800°C ; however, much further optimization is required particularly in increasing the volume fraction of second-phase particles. Alloys containing additions such as iron offer the potential for extremely high-strength levels ($>1400\text{ MPa}$ ultimate tensile strength), with possible applications as replacement for steel in components such as landing gears.

Titanium Aluminide Intermetallics. Improved ductility can be achieved by disordering, grain refinement, and deoxidation of the matrix, while good elevated-temperature properties are achieved due to a dispersion of fine, thermodynamically stable, second-phase particles. In combination with the near-net-shape advantages offered by the P/M approach, RS may offer some advantages for the processing of γ alloys over the I/M approach; presently, the same cannot be said for RS processing of α_2 -Ti₃Al alloys.

Spray Deposition

In spray deposition, finely divided molten metal droplets, produced by disintegration of a stream of molten metal using high-energy inert gases, impinge on a substrate before they completely solidify. This allows some of the characteristics of RS to be achieved in combination with a near-net-shape capability.

Dramatic enhancements in mechanical behavior can result because of the refinement in constituent particle size. An example of this is shown in Fig. 8 for 7075 aluminum. The spray deposition of titanium-base alloys also has been investigated only recently with much further development necessary.

Fig. 8 Enhanced fracture toughness in spray-deposited Al-7075

Mechanical Alloying

Mechanical alloying (MA) is a process in which heavy working of powder particles results in intimate alloying by repeated welding and fracturing. This process has the same attributes as RS: extension of solubility limits, production of novel structures and refinement of the microstructure (down to the nanostructure range); additionally, it allows production of a dispersion of second-phase particles.

Aluminum. High-temperature alloys with titanium additions, low-density alloys with magnesium additions, and extra-low-density alloys with lithium additions have been developed through MA. The mechanical property combination that can be obtained in an MA aluminum-base alloy is shown in Table 6. The MA aluminum-lithium alloys exhibit minimal degradation of properties when stressed in the transverse direction and are characterized by excellent general corrosion resistance that is $100\times$ better than that exhibited by the I/M alloy.

Table 6 Room-temperature mechanical properties of MA aluminum alloys (longitudinal)

Process	Alloy	Ultimate tensile strength, MPa	Yield strength, MPa	Elongation %	Fracture toughness (K_{Ic}), MPa \sqrt{m}	Density g/cm ³
Mechanical alloying	Al-Li-Mg-O-C	510	450	10	45	2.55
Ingot metallurgy	7075-T73	505	435	13	32	2.81

Source: Ref 2, 3

Magnesium. Mechanical alloying has been employed in the development of "supercorroding" alloys for submarine applications, such as a heat source in diver suits, and as a hydrogen gas generator.

Titanium. Mechanical alloying of titanium alloys has resulted in supersaturated solid solutions, metastable crystalline and glassy phases as well as nanometer-sized grain structures.

Titanium Aluminide Intermetallics. Work on MA of the titanium aluminides indicates that this is an interesting fabrication method for both the α_2 and γ families of alloys, resulting in the formation of surprisingly stable nanosized grains, which are stable even after compaction by HIP (Ref 17, 18, 19). In dispersoid-strengthened material in comparison to RS alloys, MA alloys exhibit finer grain structures and absence of dispersoid-free zones near grain boundaries; further dispersoids do not coarsen significantly up to very high temperatures; however further work is needed to optimize the product.

Plasma Processing

In plasma processing, solid feedstock is converted to the vapor phase at elevated temperatures due to the highly concentrated enthalpy. Chemical reactions occur, and a solid product nucleates and grows at a lower temperature. A number of studies have led to the formation of nanometer-sized metallic powders.

Vapor Deposition

Production of alloys directly from the vapor phase allows even greater flexibility in constitutional and microstructural development than RS and MA. Either monolithic material or alternate layers of two or more metals can be produced (Ref 21, 22).

Aluminum. The strength of a vapor deposited Al-7.5Cr-1.5Fe alloy is significantly higher than the strength of RS alloys up to at least 250 °C, a result of the fine microstructure produced by the vapor deposition technique. It is also possible to produce nanostructured layered structures that exhibit novel strength and modulus combinations (Ref 21, 22).

Titanium. The electron beam vapor quenching technique has been used to produce alloys that are not possible by I/M or even RS. One example is the production of titanium-magnesium alloys. Magnesium boils below the melting point of titanium making production of a liquid alloy impossible by conventional methods. Using the electron beam vapor quenching technique up to 28 wt% Mg can be alloyed with titanium. This is a potentially attractive alloy because magnesium lowers the density of titanium in excess of 1% for each 1 wt% Mg added.

Thermohydrogen Processing

Thermohydrogen processing (THP) is a technique in which hydrogen is added to a metal or alloy to enhance processing and improve final mechanical properties (Ref 23, 24, 25, and 26). To date it has only been applied to any extent to titanium-base materials. The THP technique has been used to improve the processability of alloys such as Ti-6Al-4V and to refine the microstructure with a concurrent enhancement in crack-initiation-related properties such as fatigue.

Preliminary studies have shown that the THP approach can also be used to refine the microstructure of Ti_3Al -type alloys, and the technique is being used on a pilot-plant basis at the All Union Institute for Light Alloys Moscow, Russia, to improve processability. Because of the conventionally very low solubility for hydrogen in TiAl-base alloys, use of innovative techniques such as RS are required in combination with THP.

Nanostructured Materials

Nanostructured materials are materials with at least one dimension in the nanometer range ($1\text{ nm} = 10^{-9}\text{ m}$), generally $\leq 100\text{ nm}$. Because of their novel combinations of mechanical, physical, and magnetic properties they have received considerable attention in the past few years (Ref 27, 28, 29, and 30). The nanostructures can be one-dimensional (layered), two-dimensional (fibrous), or three-dimensional (crystallites). However, the vast majority of work to date has been on the third type, which is generally produced using a P/M approach, and this article only considers this type of nanostructured material. A schematic representation of a nanostructured crystallite material is shown in Fig. 9 (Ref 27). The large fraction of atoms located in the grain boundary regions results in novel processing possibilities and enhanced combinations of mechanical, physical, and magnetic behavior compared to materials, with a more conventional grain size ($>1\text{ }\mu\text{m}$). Because of the "far-from-equilibrium" nature of nanostructured powder, compaction is a major concern, particularly retention of nanometer-sized ($\leq 100\text{ nm}$) grains.

Fig. 9 Schematic of nanostructured material. Black circles represent atoms in normal lattice positions within the grains; white circles indicate atoms that are "relaxed" in grain-boundary regions. Source: Ref 27

Methods of production of nanostructured materials have concentrated on gas condensation methods, but chemical, mechanical (e.g. mechanical alloying) and plasma (see earlier) techniques have also been used (Ref 27, 28, 29, and 30). During the MA process the powder particle size and also the grain size are continuously refined, and very often nanometer-sized grains are produced (Fig. 10) (Ref 1, 2). Not only can nanostructured grains be mechanically alloyed, but these grains do not show excessive growth during the compaction cycle (Ref 1, 2).

Fig. 10 Reduction in grain size with MA time determined from x-ray diffraction line broadening, for a number of TiAl-type alloys

Metal-Matrix Composites

Aluminum. AMC Ltd. has used a P/M approach involving mechanical attrition and HIP to achieve an exceptionally uniform dispersion of particles and consistent mechanical properties (Table 7) (Ref 1, 2).

Table 7 Typical mechanical properties for Al 2124 particle-reinforced MMC produced by the P/M route

SiC content, vol%	Elastic modulus (<i>E</i>), GPa	Ultimate tensile strength, MPa	0.2% yield strength, MPa	Elongation, %
17	100	600	400	8
25	115	700	460	7
35	135	540	450	2.5

Magnesium. A silicon carbide particulate reinforced magnesium alloy MMC has been developed for defense and automotive applications (Ref 1, 2). With a density of 2 g/cm³ and a modulus of 63 GPa, thin-walled tube can be manufactured 18% lighter than an equivalent aluminum alloy tube. The composite also has good wear resistance and a reduced coefficient of thermal expansion compared with magnesium alloys.

Titanium. A recent program on fabrication of components using the blended elemental (BE) MMC titanium approach had as its main goal development of low-cost products that could compete for automotive applications while maintaining acceptable mechanical property levels (Ref 1, 2). Expensive extra-low chloride hydride-dehydride (HDH) titanium powder and HIP are out of consideration for automobile use because of the added cost. In a recent fabrication program, titanium sponge fines, master alloy, and boron (or boride) were blended together and given a MA (kneading) treatment, followed by cold pressing and sintering. The TiB formed was judged to be the optimal reinforcement because of lack of reaction with the matrix and good physical and mechanical characteristics. The MA treatment broke up large remnant NaCl particles (100-200 μm in diameter), resulting in elimination of large pores. Mechanical properties of Ti-6Al-4V with 10 vol% TiB₂ are shown in Fig. 11 in comparison with HDH materials. The fatigue behavior is enhanced, and wear resistance is excellent. Other titanium alloys have also been shown to exhibit attractive properties fabricated using this new approach (Ref 1, 2) with 10 vol% TiB.

Fig. 11 Comparison of mechanical properties of Ti-6Al-4V + 10 vol% and HDH hot isostatically pressed Ti-6Al-4V

Advanced Automotive Use

The use of P/M parts in automobiles can only increase due to the influence of the Partnership for Next Generation Vehicle (PNGV) program. The PNGV program is a "network" between the government, the car manufacturers (USCAR: Chrysler, Ford, and GM) and Suppliers/Universities/Others with Government funding currently at greater than \$100 million per year. In summary, the goal of the PNGV program is to have all of the features of today's car, with three times the fuel efficiency, affordability, manufacturability, repairability, and recyclability (greater than 80% of the vehicle to be recyclable). Clearly, this fuel efficiency must come mainly from a vehicle weight reduction, with the body and chassis potentially showing the greater weight reductions.

In Japan, a number of automotive components have been targeted by the Japanese Titanium Society for possible titanium use. In this regard, a comparison of the manufacturing costs of low-cost titanium BE parts with wrought titanium and current steel parts is shown in Fig. 12. The material developed requires little machining and is cost competitive with current steel parts.

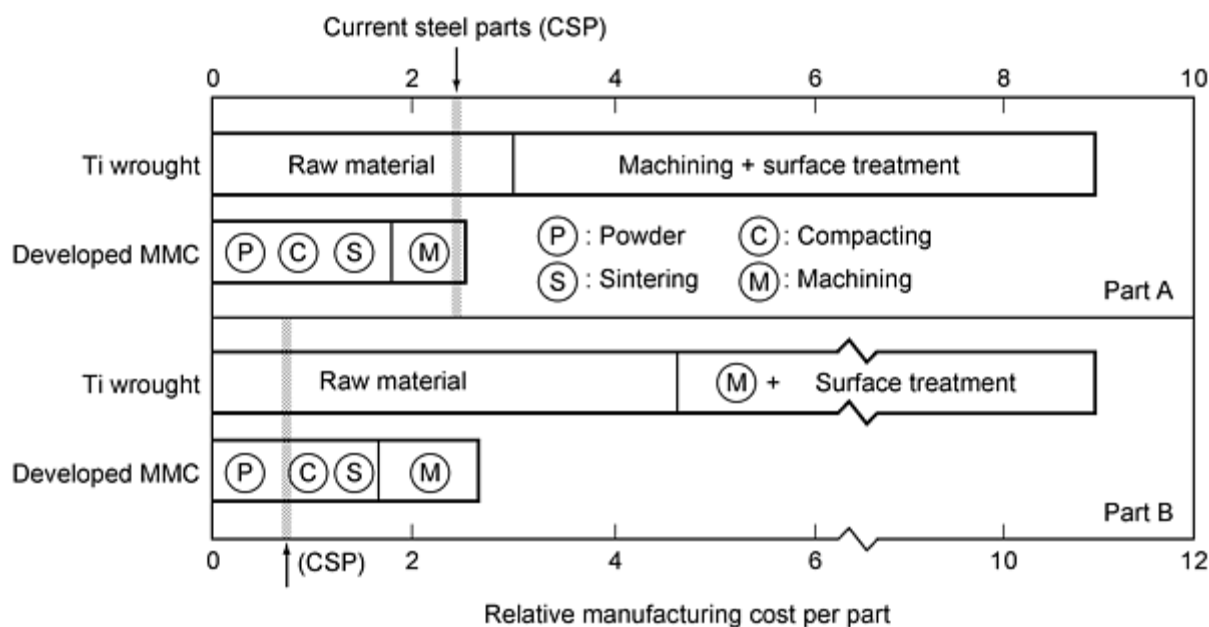

Fig. 12 Comparison of manufacturing costs of low-cost titanium BE composite parts with conventional wrought titanium and current steel parts

Use of spray-formed and extruded parts have proven to be cost effective for use in the rotors of the high-efficiency Mazda Miller cycle automotive engine (Ref 31, 32, 33, and 34). This engine results in a reduction in fuel consumption of about 20%. Future plans are to use sprayed aluminum-silicon in the connector rods, cylinders, and air-conditioning compressor of the Mazda EUNOS 800 (XEDOS 9), featuring a V-6 Miller cycle engine (Ref 31, 32, 33, and 34).

Aluminum alloy MMCs have been introduced in various automotive engine components, and applications are steadily increasing. Examples include Toyota diesel engine pistons selectively reinforced with 5% short alumina fiber (Ref 35), where the MMC leads to a weight reduction of 5 to 10%, wear reduced by four times, and seizure stress doubled; Honda cast aluminum cylinder blocks locally reinforced with 12% short alumina fiber and 9% C (Ref 36). Particulate-reinforced aluminum alloy MMCs, containing typically 15 to 30% SiC, are poised for automotive use, with promising applications including brake discs, drums, and calipers. The new Lotus Elise sports car has aluminum MMC discs for both front and rear brakes. Disc weight is reduced by about 50% compared with the alternative cast iron, and better thermal diffusivity gives increased resistance to overheating of the friction surfaces.

Powder Metallurgy Process Modeling and Design

Robert Dax, R.J. Henry, T. McCabe, and P. Barrous-Antolin, Concurrent Technologies Corporation

Introduction

CONCURRENT ENGINEERING methodologies drastically reduce or eliminate the need for trial and error methods in the design of process tooling or prototype components. Both the materials data and the analysis tools are readily available for product design activity. However, the process design activity has, in general, been hampered by a lack of readily available data on the mechanical behavior of materials under the conditions encountered during manufacturing. Furthermore, the mechanical behavior of metal powders is fundamentally different than that of metallic solids leading to the necessity to develop new process analysis tools tailored to this unique behavior. This article provides an update on process models used in the production of components by metal powder die compaction, powder injection molding, and hot isostatic pressing. More information on modeling of die compaction is in the article "Mechanical Behavior of the Metal Powders and Powder Compaction Modeling" in this Volume.

Metal Powder Compaction

In the die compaction process, shown schematically in Fig. 1, a die cavity of the desired geometric shape is filled with metal powder. Pressure, on the order of 350 to 700 MPa (50 to 100,000 psi), is applied by the axial movement of one or more punches. The pressure causes the metal powder particles to mechanically interlock and cold weld together into a porous mass of the approximate shape and dimensions desired for the final component. This as-pressed shape, commonly referred to as a green part, is then heated to an elevated temperature, on the order of 1120 to 1200 °C (2050 to 2200 °F), for 30 to 120 min to sinter the metal powder particles into a solid mass. There are several limiting factors in the use of die compaction to manufacture engineering components:

- Geometric shape is limited by the required axial movement of the punches.

- Friction between the powder particles and the tooling surfaces, combined with interparticle friction, hinders the uniform consolidation of the metal powder leading to density variations.
- Density variations in the green compacts lead to nonuniform size changes during sintering.
- Mechanical properties of the sintered components are a function of the local density variations.

However, the cost advantages of directly producing a near-net or netshape component combined with excellent part-to-part uniformity and reproducibility have made die compaction the process of choice for a wide variety of automotive, electronic, and consumer parts.

Fig. 1 Schematic of the die compaction process

The key to successfully broadening the application of die compaction to the manufacture of engineering components is the development of a meaningful constitutive description of the deformation behavior of the powder during compaction. This description is complicated, requiring knowledge of the mechanical interaction of a large number of powder particles of varying sizes that are not uniformly distributed throughout the die and including the friction effects which create density variations during the compaction process. This effort is further complicated by the functional relationship between density and the elastic and plastic properties of the compact that, in turn, affects the frictional forces.

Given a constitutive equation describing the mechanical properties of the metal powder and a description of the frictional forces between the metal powder and the walls of the tooling, numerical solution techniques can be used to solve the mechanical equations of state that describe the compaction process. For example, finite element method codes, such as NIKE (Cray Research, Eagan, MN) or ABAQUS (National Supercomputer Centre, Linkoping, Sweden) have been used to produce solutions describing these density variations. The frictional forces between the metal powder and the walls of the tooling have been estimated using descriptors incorporated into these finite element programs. The material constitutive model is usually derived from experiments simulating the compaction process. To understand the limitations

of these constitutive models, it is helpful to compare the deformation behavior of metal powder compacts with that of full density metals.

Powder Metallurgy Process Modeling and Design

Constitutive Behavior

Constitutive material models provide a mathematical description of the deformation response of the material to an applied stress. In their simplest form, constitutive material models can be reduced to the equations describing stress-strain behavior in elastic loading. In their more complex form, constitutive material models include the effects of strain (strain hardening), strain rate, temperature, microstructure, anisotropy, and time (creep or viscoelastic deformation) on the stress-strain behavior. In practice, constitutive models for full density materials are generally configured to describe the stress state required under a given set of conditions to cause plastic flow. Ideally they can, furthermore, provide quantitative measures of the final dimensions of the material body after deformation and knowledge of the final mechanical properties and microstructure. Typically, these models describe the stress state by separating it into hydrostatic and deviatoric components, as shown in Fig. 2. The hydrostatic or spherical stress component is the first invariant of the stress tensor and is equal to the average stress and opposite in sign:

$$P = -\frac{1}{3}(s_1 + s_2 + s_3) = J_1 \quad (\text{Eq 1})$$

The deviatoric or octahedral shear stress component is the second invariant of the stress tensor and represents the effective shear stress developed by the applied stresses:

$$J_2 = \frac{1}{3}[(s_1 - s_2)^2 + (s_2 - s_3)^2 + (s_3 - s_1)^2]^{\frac{1}{2}} \quad (\text{Eq 2})$$

The hydrostatic stress is related to the volume change of a fully dense material; the deviatoric stress is related to the distortion or shape change of a fully dense material.

Fig. 2 Separation of generic stress state into components. Source: Ref 1

A familiar example of a constitutive model for a full density material is the von Mises yield criterion which predicts the onset of plastic deformation when the deviatoric stress reaches a set or constant value determined by the nature and condition of the material in question:

$$J_2 = C_1 \quad (\text{Eq 3})$$

A plot of this criterion in three-dimensional principle stress space, as shown in Fig. 3, produces a regular right cylinder which defines the yield surface. All values of principle stresses lying on (or outside) the surface of the cylinder produce plastic flow. This surface degenerates into the familiar von Mises yield ellipse for two-dimensional stress plots. If the material work hardens during plastic flow, the diameter of the cylinder expands, thus indicating higher values of stress are required to produce additional plastic flow.

Fig. 3 von Mises yield surface in three-dimensional stress space. Source: Ref 1

The graphical depiction of the von Mises yield criterion can be simplified by plotting the von Mises criterion as a function of the deviatoric and hydrostatic stress components as shown in Fig. 4. Plastic flow occurs for all stress states located on (or above) the dotted line. If the material workhardens, the yield surface moves progressively to higher values of J'_2 . Using J'_2 - P space to plot the yield criterion clearly shows that yielding is determined by the deviatoric stress component (J'_2) and is not affected by the hydrostatic stress component (J_1).

Fig. 4 Plot of yield criteria in J'_2 - P space. Source: Ref 1

The deformation response of metal powders to an applied stress is considerably more complicated than that of solid metals. This response may be categorized into two regimes (Ref 1): (a) an aggregate of loose particles during the early stages of consolidation, and (b) a porous body at the latter stages of compaction.

During the initial stages of compaction, the densification of aggregates of loose particles occurs by particle reorientation and sliding. As compaction continues, localized particle deformation occurs at the particle contact points. As compaction continues, particle yielding occurs on a broader basis leading. At this stage of compaction, the powder compact begins to deform as a porous body.

During densification, the compaction pressure increases as the resistance of the metal powder compact increases. At low compaction pressures, particle sliding is the operative mechanism and large increases in density per unit compaction pressure occur. Later in the compaction process, the particle rearrangement and packing associated with the sliding mechanism is inhibited and particle deformation begins to occur. Higher compaction pressures are required to continue densification due to the need to locally exceed the flow stress of the powder particles. Thus, the rate of densification per unit compaction pressure is reduced.

The constitutive behavior of metal powder compacts will be distinctly different from that of the parent metallic material. The presence of the pores in the structure allows the creation of localized shear stresses under hydrostatic loading leading to plastic flow. Thus, the yield surface will show dependence on both the deviatoric and the hydrostatic stress components. Figure 4 also presents a typical plot of the yield surface of a powder compact as a function of the pressure and deviatoric components of stress. Because the yield surface has become a segment of an ellipse, which is a function of both the hydrostatic and deviatoric components of stress, both shape change (distortion) and volume change (densification) will occur during yielding of powder materials. The Normality Flow Rule requires that the direction of the plastic strain increment be perpendicular to the yield surface. Thus, the plastic strain increment, $d\epsilon$, can be viewed as two components, a volume strain increment, $d\epsilon_v$, parallel to the direction of the pressure and a distortion strain increment, $d\epsilon_d$, in the direction of the deviatoric stress component. Because the volume strain increment is in the same direction as the pressure, the volume of the compact is reduced by that increment.

As the metal powder compact hardens, the elliptical yield surface will move to higher levels of deviatoric and hydrostatic stress combinations. This hardening or increase in flow stress is due both to densification of the porous body and work hardening of the individual metal powder particles. Thus, during compaction, the yield surface of the metal powder compact in J_2 - P space can be represented by a family of ellipses as shown in Fig. 5. For points to the right of the line marked "Critical state line," the volume strain increment, $d\epsilon_v$, will be in the same direction as the pressure and the volume of the compact is reduced by that increment. For points to the left of the same line, the volume strain increment is in the opposite direction to the pressure and the volume of the compact is increased by that increment. This strain produces a decrease in density called shear dilatancy and describes a stress state under which a metal powder compact will fail. The point on the yield surface that divides the dilatancy region from the densification region is called the *critical state*. As densification occurs, the locus of critical state values traces the path defined as the *critical state line* that represents the limiting values of J_2 and J_1 for shear dilatancy.

Fig. 5 Family of yield surfaces representing increasing densification. Source: Ref 1

The yield or flow stress (YS) of a metal powder during compaction can be related to the deviatoric (J_2) and hydrostatic (J_1) components of the stress state (Ref 2, 3) as follows:

$$AJ_1^2 + BJ_2 = C(YS)^2 \quad (\text{Eq 4})$$

where the coefficients, A , B , and C , are functions of relative density and the degree of cold work that has been induced into the powder during compaction. This general equation describes an elliptical yield surface in J_2 - J_1 space as shown in Fig. 4 and 5. The application of this constitutive relationship in describing the deformation or compaction of a metal powder is dependent on incorporating experimentally verified flow stress data into a finite element code capable of handling the large strains associated with metal powder consolidation. Because these codes generally calculate stresses based on displacements or strains, experimentally verified data relating the elastic properties as a function of green density are needed to accurately predict the onset of plastic flow.

Materials Data Requirements

Traditionally, the deformation characteristics of metal powders were analyzed by determining the green density as a function of pressure by running a series of die compaction tests. Specialized techniques were required to minimize the effects of friction on green density. However, these tests were flawed by the inability to vary the state of stress under which compaction was occurring.

The Advanced Metalworking System, described elsewhere (Ref 1, 4), is an experimental apparatus which permits a variety of metalworking tests including direct, indirect, and hydrostatic extrusion, isostatic compaction, and triaxial compaction. It has been employed to evaluate the triaxial compaction of metal powders and provides independent control of pressure and the superimposed axial stress.

Triaxial compaction testing can be described schematically as shown in Fig. 6. The metal powder to be tested, either precompacted or loose fill, is placed in an elastomer sleeve which uses two solid metal anvils as closures. After the chamber has been filled with fluid and sealed, but prior to pressurization, the powder filled elastomer sleeve is moved in contact with the load cell (fixed platen assembly). An annular ram assembly is then advanced to pressurize the fluid environment in the chamber. The superimposed axial stress is then applied to the specimen by applying an axial force through advancement of the force stem portion of the annular ram assembly, thus, creating a triaxial state of stress. During this stage, the annular ram withdraws to keep the fluid volume constant and maintain a constant environmental pressure in the chamber. The hydrostatic chamber pressure is measured with the force stem, while hydrostatic pressure load plus the superimposed axial load is measured by the load cell pin. The positions of the main and secondary rams in the annular ram assembly are measured using LVDTs.

The data are usually analyzed by two methods. Figure 7 presents schematically the volumetric, axial, and radial strain measurements for a metal powder specimen plotted as a function of total axial stress (axial pressure component plus the applied axial stress). For this example, a hydrostatic pressure of 103 MPa (15 ksi) has been applied prior to applying the superimposed axial stress. Thus, the radial and axial strains are equal from zero stress to 103 MPa (15 ksi), and then deviate as the superimposed axial stress is increased. The radial strain is calculated from the measured values for axial and volumetric strains.

Fig. 6 Schematic representation of triaxial testing

Fig. 7 Schematic strain data from triaxial testing of metallic powder

Given the initial density of the metal powder specimen, the strain data can be used to calculate the relative density of the specimen at any point during the test. Thus at any point during compaction testing, the density values can be related to the flow stress of the powder compact. By separating the state of stress into hydrostatic (pressure) and deviatoric (axial compression) components, these data can be used to generate isodensity yield surfaces. Typical data are shown in Fig. 8.

Fig. 8 Experimentally determined yield surface for metallic powder. Source: Ref 4

Mechanical measurement of elastic properties of green metal powder compacts has, in general, been unsuccessful. The strength of the green structure, while sufficient to allow handling in manufacture, is insufficient to permit the use of conventional tensile testing techniques. Similarly, the ductility of the green structure is insufficient to permit the use of compression testing techniques. Resonant frequency testing methods can be used to evaluate elastic properties of green powder specimens (Ref 5).

A transducer is used to induce vibrations in the powder specimen. A second transducer is used to measure the intensity of those vibrations as a function of frequency. The frequency at which the maximum intensity occurs is referred to as the resonant frequency and is related to the density and elastic modulus as follows:

$$f_R = KE/r \quad (\text{Eq 5})$$

where K is a factor that accounts for the geometric aspects of the specimen. Figure 9 represents data showing Young's modulus and shear modulus as a function of density for green specimens pressed from iron powders.

Fig. 9 Young's and Shear moduli as a function of density for green compacts

Die Compaction Process Simulation Model

The finite element method is commonly applied to metalworking deformation processes to predict the stress state present in the component during manufacture. This method involves dividing the component into very small, but finite, regions following a set procedure based on the rules of application of the particular finite element methodology being used. This technique allows replacing a set of differential equations describing the overall constitutive behavior of the material with an equivalent but approximate set of algebraic equations which describe the material behavior locally at a fixed nodal point. By writing algebraic equations for each nodal point and then using the computer to simultaneously solve those equations for all nodal points, a solution describing the local values of the characteristic of interest can be generated. This solution may provide a strain map, show temperature gradients, or areas of isostress.

These methods have been widely applied to evaluate the state of stress or the temperature distribution in a component, such as a turbine blade, during its use. However, the application of this technique to processing is complicated by the requirement that some nodes may be required to slide past others, for example to describe the flow of metal along the surface of a forging die. Furthermore, this sliding may require incorporation of dynamic friction conditions. Both of these situations present serious programming problems to the finite element analyst.

The use of finite element techniques to describe metal powder die compaction is complicated by the large strains which occur during compaction--strains which exceed those that can be accounted for using traditional stress analysis finite element techniques. This distorts the geometric grid and deleteriously affects the predictive capabilities of the finite element system. Thus it becomes necessary to define a new nodal pattern after partial compaction has occurred. This remeshing is quite tedious and time consuming leading the necessity to develop techniques which automatically remesh. The application of finite element techniques to metal powder die compaction is further complicated by the nonuniform movement of the powder particles during compaction creating a variation in density throughout the compact. Both the load transfer characteristics within the metal powder compact and the nature of frictional behavior between the powder compact surface and the die wall are a function of density. These functional relationships with density are unknown and difficult to account for in the existing finite element methods.

Recent work has focused on incorporating the elasto-plastic constitutive equations for metal powder deformation into a finite element methodology. Figure 10 presents density gradient predictions for simple right cylinders of varying aspect ratios. Although the effects of friction have not yet been fully incorporated, the model predicts density variations consistent with the experimental results published in the literature.

Powder Injection Molding

Powder Injection Molding (PIM) is a net-shape processing technique for making complex metal and ceramic components. In the PIM process, a metal or ceramics powder, mixed with a suitable carrier, is injected into a die cavity in a manner similar to plastic injection molding (Ref 6).

The process uses a feedstock that is composed of fine (typically $<20\ \mu\text{m}$) powder particles blended with waxes and polymers. After injection, the green preform shape is ejected from the die cavity and then subjected to a debinding process to remove the polymeric material prior to sintering. This extraction of the binder can be accomplished by thermal or chemical means. The resulting porous shell (approximately 65 to 70% of theoretical density) is heated to 1200 to 1370 °C (2200 to 2500 °F) for 30 to 120 min to sinter the metal powder particles into a solid mass. The resulting component is about 30 to 35% smaller in volume than the molded component and typically 96 to 98% of theoretical density.

This process offers two significant advantages over die compaction. The geometric shape is not limited by axial punch movement, and the mechanical properties of the sintered component are generally higher, primarily due to a higher final density. However, powder injection tooling is generally more expensive than die compaction tooling and the size of parts that can be made is limited by the difficulty of removing the polymeric carrier without damaging the integrity of the green preformed component. Powder injection molding presents an economical route to mass produce small complex shaped parts (typically less than 50 g) that are difficult to form or machine by conventional methods.

In PIM, the mold filling phase is the most critical step in the manufacture of a part. Defects, such as sink marks, voids, weld lines, and density variations, can occur from poor tooling design or improper selection of processing parameters, such as injection temperature and pressure. Traditionally, the design of PIM process tooling, as well as the selection of processing parameters, has been made by expensive and time consuming trial and error procedures. An efficient way to reduce these costs and improve the design to manufacture cycle time is through the use of process simulation. Parametric studies of the injection variables can be conducted by computer simulation. The results of these studies provide guidance in process planning and reduce process development time.

The determination of a meaningful constitutive description of the flow behavior of the polymer/powder mixture during injection is a key to successfully broadening the application of powder injection molding to the manufacture of engineering components by using computer simulation as a tool. This description is complicated, requiring knowledge of two phase non-Newtonian flow that incorporates the effect of local shear rate on viscosity and the effect of viscous heating on the temperature distribution in the component.

These constitutive equations describing viscous flow can be used to solve the conservation of heat, mass, and momentum equations that describe fluid flow. For example, finite difference methods have been used to produce solutions describing the flow during the filling of the mold and the subsequent temperature gradients developed during cooling.

Constitutive Behavior. The mathematics of describing the constitutive behavior of the molten polymer-particulate mixture has been presented elsewhere (Ref 7). In essence, by combining the solution of the mathematical description of the flow with certain geometric constraints, the relationship between stress and displacement, the constitutive behavior, can be quantitatively described.

Thus, powder injection molding is viewed as a fluid flow problem where classical equations of state can be used to describe the behavior of the polymer-particulate mixture. The melt is assumed to be incompressible and the governing differential equations for the conservation of mass, momentum, and energy are known from first principles. These governing differential equations are solved by assuming an appropriate viscosity model (for polymer-powder particle mixtures, viscosity is assumed to be a function of shear rate and temperature) and incorporating appropriate values for key materials properties, such as density, specific heat, and thermal conductivity.

Two additional process characteristics are incorporated into this mathematical description--the volume fraction of the mold that is filled by the melt and the volume fraction of the molten material that has solidified. By tracking the volume fraction of the mold that has been filled at a given time, and relating that volume to the velocity vector for the flow system, the location of the melt front can be calculated at any time during fill. Similarly, by assuming that the solidification rate is proportional to the liquid fraction of the polymeric binder and proportional to the square of the undercooling of the melt, the solid fraction of solidified polymer can be calculated at any given time. Coupling this calculation with the thermal equilibrium requirements provides the basis for determining the location of the liquid/solid interface at any time throughout the die cavity.

Powder Injection Molding Process Simulation. During the last decade, many process modeling techniques have been developed in material processing. Tremendous success has been achieved in the development and application of process modeling technology in molten metal operations. Both the finite difference method and the finite element method have been used successfully in casting processes that involve filling a sand or metal mold with molten metal to produce parts with complex three-dimensional (3-D) geometries (Ref 8, 9, 10, 11, 12, and 13). Considerable progress has also been made in modeling polymer and powder injection molding processes (Ref 14, 15, 16, and 17). Most of polymer processing and PIM models have been based on the generalized Hele-Shaw model for thin cavities. This may be adequate for modeling parts comprised of thin-wall sections, but may not be effective for modeling general parts with arbitrary complex 3-D geometries. Development of a general program capable of simulating the PIM process in arbitrary 3-D geometries has become increasingly imperative. This could be accomplished by using either the finite element method (FEM), the finite difference method (FDM), finite volume method, or a combination of them. Generally speaking, the FEM technique gives a more precise description of the geometry, and possibly more accurate results than FDM. However, FEM requires greater memory storage, more complicated programming, and longer computing time. Hence, the finite difference technique has been applied in this article.

The PIM simulation model is based on an existing casting simulation program which models the mold filling and solidification of general 3-D metal castings. This casting model was modified to include special features, such as viscous heating, associated with the PIM process. In essence, the geometric shape to be analyzed, the component, is divided into a large number of brick-type cells. Finite difference formulations are written for each equation included in the descriptive set incorporated into the constitutive behavior equations. These equations are then solved simultaneously leading to a coupled analysis of velocity, temperature, shear rate, and mass transfer (Ref 7).

The finite difference method is similar to the finite element method in that it provides a means for converting a partial differential equation into a set of algebraic equations. It differs from the finite element method in that the region of interest is divided into n discrete intervals or control volumes at which values of the differential equation are approximated using mathematical techniques such as a Taylor series expansion. Although some accuracy may be lost because stepped rectangular cells are used to represent sloped boundaries, the FDM technique allows the use of a large number of cells (elements) because of its simplicity in programming and efficiency in computing. For a given amount of computer memory, the FDM method can compute values for 20 to 50 times more cells than the FEM technique. As such, it is capable of describing small localized phenomena and large thermal or velocity gradients. Thus, it is especially suitable for modeling PIM and polymer processing where the thermal and momentum gradients are large due to low thermal conductivity combined with a rapid filling rate.

In the computing technique incorporated into the model, the complete partial differential equations describing the PIM processes are solved implicitly by the finite difference method. The technique takes into account the time-dependent non-Newtonian fluid flow behavior with free surface and viscous heating phenomena in arbitrary 3-D geometries. The complex 3-D domain is subdivided into small brick-type cells. Sloped surfaces are approximated in a zig-zag fashion. A uniform mesh is used throughout the model. The typical number of cells used for an industrial part is approximately 100,000 to 500,000. The discrete values of the velocity components are located at cell faces, while all other variables are located at the centers of the cell (Ref 8). Useful information, such as flow front locations, distribution of velocities, temperature, shear rates, and weld lines are obtained through the simulation. Figures 11 and 12 compare the flow fronts from an injected part (Fig. 11) and the numerical simulation of the injection process (Fig. 12).

Fig. 11 Experimental results showing flow front location at different times during filling. Injection melt temperature is 138 °C and initial die temperature is 24 °C. (a) to (d) represent increasing time. Source: Ref 18

Fig. 12 Numerical simulation results showing flow front locations at different times during filling under similar conditions to Fig. 11. Injection melt temperature is 130 °C, initial die temperature is 25 °C, and injection pressure is 3 MPa, with sufficient venting. Source: Ref 18

There are several advantages of the computational and modeling techniques used:

- No term of the momentum and energy transport equations is neglected in the formulation. The partial differential equations are solved as they appear in their original forms, so that the model is capable of predicting any flow configuration, including jetting phenomena.
- The model can readily analyze general three-dimensional geometries.
- The finite difference method (FDM) is used.
- As a result of the simplicity in the formulation and the computation of this technique, the input of the geometry and the meshing of the part are much easier than with FEM techniques.

Several assumptions and simplifications are made to streamline this modeling technique. Variations in density and the heat capacity of feedstock and mold materials are assumed negligible in space and time. The solidification rate of the feedstock is assumed proportional to the square of the degree of undercooling and proportional to the liquid fraction of the binder material. Perfect contact is assumed between the feedstock and the mold during filling, so that heat transfer at the melt-mold interface is controlled by conduction. Heat transfer from the melt to the air in the mold cavity is assumed negligible since the filling time is short and the heat capacity of the air per unit volume is small.

Hot Isostatic Pressing

Hot isostatic pressing (HIP) modeling is based on a phenomenological constitutive relation for powder consolidation under high pressure and high temperature. The consolidation of metal powders via HIP can produce cost-effective, high-quality, and high-performance components. The advantages of HIP processing over casting include a uniform, fine grain structure without shrinkage porosity, inclusions, and segregation; a decrease in machining time due to making parts nearer to net shape and with a finer microstructure; and reduced residual stresses that can cause parts to undergo distortions during finish machining. In spite of these advantages, the cost-effective manufacture of parts with complex shapes via HIP has been hindered by difficulties in achieving suitable dimensional control.

Currently, the containers that hold the powder and define the component shape are designed by trial and error; this is very costly and time consuming. In each iteration, the container is redesigned and another part is HIPed to determine the effect of the design modification. Depending on part size and alloy, the cost can exceed \$100,000 per trial (1998 dollars), and each iteration can take months to complete. To reduce costs associated with shape control by trial and error, it is necessary to accurately predict the final shape of the as-HIPed component during the design stage.

With computer models that accurately predict the as-HIPed shapes, simulations may replace actual HIP trials, thereby reducing the expense of container design and the lead times for new components. Using a computer model, a container design iteration could be measured in days or weeks rather than months, and the cost of actual HIP trials would be saved.

General Conditions of HIP Modeling. The HIP method is essentially a thermomechanical process. In HIP, powder consolidation and heat transfer occur simultaneously. The physical mechanisms involved in the powder consolidation include plastic yielding, creep, and diffusion. The local stress and temperature in the powder compact govern the contribution of these mechanisms to the powder consolidation. Heat transfer (mainly heat conduction) in the powder compact is strongly influenced by the local relative density. Therefore, the analysis of HIP is a coupled thermomechanical analysis.

Modeling the HIP process requires the solution of a boundary value problem described by:

- Equation of motion
- Conservation of mass/continuity equation
- A set of constitutive equations
- A proper set of initial and boundary conditions

To fully specify the constitutive model of the powder and can material, a variety of experiments should be performed. The testing approach and data analysis is described in the next section. Prior to discussing the constitutive model, it is also important to distinguish between the microscopic (powder particle) deformation associated with individual particles and the macroscopic (powder aggregate) deformation of the powder aggregate idealized as a continuum. At the macroscopic level, field variables such as stress and strain are defined over a small representative material element containing enough particles to qualify for a macroscopic regime. Clearly, an exact solution of these field variables would require the solution of a boundary value problem involving the exact number, shape, and size of these particles. At the microscopic level, the field variables of each particle are obtained in some average sense. Thus, the particle quantities are defined as those obtained by averaging the actual particle values (obtained from the unified theories of dislocation driven plasticity for isotropic materials) over the macroscopic material element. These two modes of deformation, which constitute the basic philosophy of the proposed methodology, facilitate the tracking of internal state evolution of the material as a whole and the individual particles in some average sense. Details of the development of the viscoplastic constitutive model for the densification of metal powders during HIP have been reported previously (Ref 19, 20). Additional information is also contained in the article "Principles and Process Modeling of Higher Density Consolidation" in this Volume.

Constitutive Model. Power-law creep represents the flow behavior of the container material. The flow behavior of the powder is represented as a combination of the particle flow behavior and the powder aggregate flow behavior described by the following macroscopic, viscoplastic potential function or yield function, ϕ (Ref 19, 20). This function represents the evolution of yield loci as a function of relative density:

$$\phi = S^2 + bp^2 - cs^2 = 0 \quad (\text{Eq 6})$$

where S is the magnitude of the deviatoric stress in the powder aggregate, s is a measure of the deviatoric stress in the powder particle, p is the pressure, and the parameters b and c are functions of relative density to be determined from experiments.

Based on this constitutive model, the following material properties are required:

- Flow behavior of the particles
- Constitutive functions. $b(\rho)$ and $c(\rho)$ for the powder aggregate
- Specific heat of the powder as a function of temperature
- Thermal conductivity of the powder as a function of density

In addition, the accuracy of the model must be verified by some basic finite element simulations and empirical testing. The experimental tests are required to fully specify the constitutive model of the powder and can material. The experimental characterization of powder determines the flow behavior of particles and the constitutive functions of the aggregate.

Partial HIP Testing. The macroscopic solution of the boundary value problem involving powder aggregate under hydrostatic pressure can be obtained from the analytical expression given below and the power-law creep model for the particle flow behavior. The corresponding density evolution takes the form:

$$\dot{\rho} = A \exp\left(-\frac{Q}{RT}\right) \left(\frac{3}{2}\right)^{(n+1)/2} p^n \left(\frac{b(\rho)}{c(\rho)}\right)^{(n+1)/2} \rho^2 \quad (\text{Eq 7})$$

This differential equation can be numerically integrated to obtain a distribution of densities at different applied temperature and pressure cycles. As can be seen from Eq 7, the rate of change in density strongly depends on the temperature and pressure. Other important characteristics of Eq 7 are a threshold value of temperature below which the dependency of density rate on the pressure is weak and a range of pressure magnitude below which the rate of change in the density weakly depends on the temperature. The understanding of this interaction between the temperature and pressure dependence can be very important in avoiding HIP cycles that cause densification to occur too quickly, which could cause a densification front to form, or too slowly, exposing the material to elevated temperature longer and limiting productivity. However, the overall objective is to derive accurate material properties using a series of interrupted HIP cycles at different dwell times to produce density distributions ranging from a low relative density (about 75%) up to full density.

Effects of Container. There are several reasons for distortion of the final geometry, which can be directly related to the preparation of the container. Some of these reasons include incomplete filling and degassing of the powder, poor powder quality, and nonuniform can thickness including thick and thin regions near welds. Even if these problems are corrected and the powder filling operation is sound, inhomogeneous compaction rates will always prevail due to the uneven resistance offered by different sections of the container, such as at corners. The thickness of the container provides shielding of the gas pressure in the HIP unit. To properly account for this difference between the gas pressure and the effective pressure inside the powder, a numerical scheme based on the flow properties of the container at different temperatures and strain rates has been developed and incorporated into the material model. Details of this derivation have been reported previously (Ref 21). Unlike pressure, temperature shielding due to the container thickness was found to be negligible, and thus, was not considered. It should be emphasized that this shielding effect is more pronounced in bulky parts where temperature and pressure gradients can be significant.

Calibration and Experimental Verification. Calibration of a HIP material model for the powder aggregate involves the following steps:

1. Obtain partially HIPed compact bars with short HIP cycles not exceeding the rate of temperature or pressure application for actual HIP production cycles
2. Machine the partially HIPed bars into compression specimens
3. Measure the density of every compression specimen
4. Calculate the pressure correction factor (effective pressure applied to the powder aggregate as opposed to the gas pressure applied by the HIP vessel on the outer wall of the container) (Ref 21)
5. Calculate the relationship between relative density and HIP temperature and pressure
6. Perform compression tests on specimens with different densities at different strain rates and temperatures
7. Correct true stress-true strain curves to account for volume change during compression testing
8. Measure the density of compression specimens and obtain a relationship between axial stress and final density for each specimen
9. Using results from above, calculate the functions $b(\rho)$ and $c(\rho)$ that represent the weighting coefficients in the deformation macroscopic potential function (Ref 21)
10. Measure thermal conductivity and specific heat on partially HIPed and fully dense material over a range of relative densities and obtain a relationship between relative density and thermal conductivity for a temperature range of 25 °C to the HIP temperature

The following sections describe the partial HIP testing, isothermal compression tests, and thermophysical properties measurement used in the evaluation of the power-law creep parameters and the ratio of constitutive functions, $b(\rho)/c(\rho)$ for Alloy 625.

Compression Tests of Fully Dense Alloy 625. Tests were conducted on a servohydraulic testing system with a vacuum furnace. To avoid possible oxidation of the specimens during testing, a vacuum environment at 10^{-4} torr or lower was used. A computer should control the testing system with a data acquisition system employed to perform true strain rate tests under stroke control. Load and stroke data are required and converted to true stress and true strain by assuming constant volume of the specimen during deformation. A boron nitride treatment is applied to the grooved ends of the specimens and the compression platens. Experiments show that lubrication of both the specimen and the platens greatly reduced the friction and enabled uniform deformation during compression. The specimens are heated in a vacuum furnace to test temperatures ranging from 260 °C to 1149 °C. Prior to testing, the specimens are soaked at the testing temperature for three minutes to avoid a thermal gradient. Subsequently, the specimens were uniaxially compressed to a total true strain of 0.6 (60%). Immediately after the compression test, the specimens are quenched with forced helium gas to retain the deformed microstructure.

Compression Tests of Partially Dense Alloy 625. Compression testing is also required on partially dense materials in order to determine the thermomechanical behavior of the aggregate powder. Specimens with minimum initial relative density (75%) are compressed from a true strain of 0.2 (20%) to a true strain of 0.8 (80%). Three additional specimens with initial relative densities of approximately 83%, 90%, and 96% are used to complete the curve of axial stress versus density in the high-density regime. After the tests, specimens are immediately quenched with helium gas to retain the deformed microstructures.

Unlike fully dense material in which the volume of the specimen remains constant, the powder compacts densify during the compression testing. To account for this, conservation of mass is used in the calculation of true stress-true strain. From the converted true stress-true strain data, a relationship between uniaxial stress and relative density was obtained.

Thermophysical Tests. Four partially HIPed test specimens should be tested for thermophysical properties between room temperature and 1150 °C. Thermal diffusivity (α) values are measured using a technique such as laser flash. A differential scanning calorimeter (DSC) should be used to measure specific heats. Testing is conducted under vacuum to reduce oxidation of the test samples. Thermal conductivity (λ) values were calculated from the following:

$$\lambda = \alpha C_p \rho \quad (\text{Eq 8})$$

where ρ is the material bulk density.

A range of relative densities of specimens, such as 0.72, 0.78, 0.90 and 1.0, are needed. Thermal conductivity results showed a strong dependency on the relative density mainly in the high temperature regime. It is also important to note that the conductivity values increase well above the transformation temperature.

The thermal conductivity of the aggregate powder, $\hat{\kappa}(\rho, T)$ is a function of both density and temperature. This function can be expressed as a product of two functions:

$$\hat{\kappa}(\rho, T) = \hat{R}(\rho)\hat{\kappa}_p(T) \quad (\text{Eq 9})$$

where, $\hat{\kappa}_p$ is the thermal conductivity of the powder particle, and \hat{R} is a function that depends only on the relative density.

Calibration of a Power-Law Creep Equation for Fully Dense Materials. A series of uniaxial isothermal compression tests are needed on fully dense material of the alloy powder. The test conditions, temperature, and strain rate should be chosen to be within the diffusion creep regime for the material.

The power-law creep is usually described in the following form:

$$\dot{\epsilon} = A \exp\left(-\frac{Q}{RT}\right) \bar{\sigma}^n \quad (\text{Eq 10})$$

where, Q , R , and T are the activation energy, universal gas constant, and absolute temperature; and $\dot{\epsilon}$ and $\bar{\sigma}$ are the average strain rate and flow stress, respectively. A and n are the creep parameters.

There are several ways to estimate the activation energy. In one way, two compression tests are conducted. The first is at constant temperature with a rapid increase in strain rate, and the second is conducted at constant strain rate with a rapid decrease in temperature.

For the two tests with equal temperatures ($T_1 = T_2$), Equation 10 could be rearranged to obtain n as follows:

$$n = \ln(\dot{\epsilon}_1/\dot{\epsilon}_2)/\ln(\sigma_1/\sigma_2) \quad (\text{Eq 11})$$

Similarly, for two tests with equal strain rates ($\dot{\epsilon}_1 = \dot{\epsilon}_2$), rearrangement of Eq 10 yields the following expression for Q :

$$Q = nR \ln(\sigma_1/\sigma_2)/[(T_1 - T_2)/T_1 T_2] \quad (\text{Eq 12})$$

To fully describe the power-law creep behavior of alloy 625 (Eq 10), the only parameter left to be determined is A . However, for consistency, both A and n were obtained using the following procedure which took into account a wider range of strain rates typical of those found in the HIP process. Equation 10 was rearranged as follows:

$$\dot{\epsilon} \exp(-Q/RT) = A \sigma^n$$

or

$$Z = A \sigma^n \quad (\text{Eq 13})$$

where Z is the Zener-Hollomon parameter. Equation 13 can be plotted using the strain rate, temperature, and flow stress data from the compression tests of the fully dense Alloy 625. The data are then fitted to a power-law distribution, and thus the power-law constants A and n are identified.

Introduction to Metal Powder Production and Characterization

Yves Trudel, Quebec Metal Powders Limited

Introduction

METAL POWDER PRODUCTION techniques are used to manufacture a wide spectrum of metal powders designed to meet the requirements of a large variety of applications. Powders of virtually all metals can be produced. Various powder production processes allow precise control of the chemical composition and the physical characteristics of powders and allow tailoring of specific attributes for targeted applications. Development and technical innovation in metal powder production processes are constantly pursued to meet the quality, cost, and performance requirements of existing and emerging applications.

Introduction to Metal Powder Production and Characterization

Yves Trudel, Quebec Metal Powders Limited

General Methods of Metal Powder Production

Metal powders are produced by mechanical methods or chemical methods. The commonly used methods include water and gas atomization, milling, mechanical alloying, electrolysis, and chemical methods including reduction of oxides.

Suitable methods for powder production depend on required production rates, powder properties, and the physical and chemical properties of the material. Chemical and electrolytic methods are useful for producing high-purity powders. Mechanical comminution (or milling) is the most widely used method of powder production for hard metals and oxides. Secondary milling of oxide-reduced, atomized, or electrolytic powders is also a very common and economical practice. Nonetheless, mechanical comminution can be a limited method of metal powder production due to the ductility of most metals (although hydriding is a technique that can enhance powder production by milling for some metals, see the article "Milling of Ductile and Brittle Materials" in this Section).

Atomization is perhaps the most versatile method that produces metal powders over a wide range of production rates (from 1 to 10^5 tons/yr) and a wide variety of powder sizes from 10 to 1000 μm (Ref 1). Typical particle sizes for atomized metal powders are summarized in Fig. 1, and more detailed coverage on the basic principles of atomization are detailed in the next article in this Section. Nonetheless, a growing number of P/M applications (Fig. 2) require submicron powder sizes that are produced by chemical or physical means. Ultrafine (i.e., submicron) powders cannot be effectively produced by grinding or conventional (gas and/or liquid) atomization. Some basic physical and chemical methods of ultrafine powder production are discussed in the article "Ultrafine and Nanophase Powders" in this Volume.

Fig. 1 Approximate ranges of useful particles size and world production of different melt-atomized alloys. Source: Ref 1

Fig. 2 Some ranges of useful particle size for different applications of metal powders. Source: Ref 2

Another article also discusses powder blending and mixing techniques, including the recently developed binder-treatment blending used for metal powders. Binder-treated premixes (Fig. 3) lead to reduced dusting and segregation of alloy additions and enhanced powder flow and die filling. This results in improvements in density uniformity, weight variation, alloy homogeneity, and dimensional control of P/M parts.

Introduction to Metal Powder Production and Characterization

Yves Trudel, Quebec Metal Powders Limited

Ferrous and Nonferrous Powders

Metal powders produced by mechanical and chemical methods are summarized in Fig. 4 and 5, respectively. Ferrous powders are of prime importance to the P/M industry because they account for more than 80% of all powder shipments (tonnage). The production and usage of iron and steel powders in North America has grown at a compounded rate of about 6% per year from the mid-1980s to the mid-1990s, reaching more than 350,000 tons in 1996. The production of iron and steel powders in Japan and Europe during the same year was 173,000 and 114,000 tons, respectively.

Fig. 4 Mechanical methods of powder production. Source: Ref 3

Fig. 5 Chemical and electrochemical methods of powder production. Source: Ref 3

Most ferrous powders are currently produced by water atomization of liquid steel. This process, pioneered in the 1960s by the A.O. Smith Company, has since been adopted by the main iron and steel powders producers in North America, who have developed a wide spectrum of elemental and prealloyed powders designed for specific needs of P/M and powder forging applications. The techniques used to manufacture stainless steel powders, tool steel powders, and high-alloy materials are also described in the Section of this Volume devoted to the production of iron and steel powders.

The production of nonferrous powders is covered in this Section. Copper and copper-base powders, aluminum powders, nickel powders, and tungsten powders are among the many types of metal powders whose production techniques are described and discussed.

Introduction to Metal Powder Production and Characterization

Yves Trudel, Quebec Metal Powders Limited

Powder Characterization and Testing

Reliable techniques for powder characterization and testing are required to evaluate the chemical and physical properties of metal powders, both as individual particles and in bulk form. This is important to ensure adequate control of powder production processes and to ensure that the required properties for parts manufacturing are met. This Section also features a series of articles on characterization and testing of powders.

The representativity of samples taken to test metal powders is key to the characterization process. The required sampling techniques that ensure such representativity are discussed. The various techniques for analyzing the chemical composition of metal powders are described, together with specific testing procedures that characterize the physical properties of powders. These include particle size distribution, particle shape, and surface area. Each of these parameters may have a significant effect on the physical and mechanical behavior of powders used for the manufacturing of P/M parts. Bulk properties of metal powders are also discussed in this Section.

A description of test methods for apparent density, a critical property for ensuring part-to-part weight consistency, and powder flow rate is included. Finally, an article describes test methods for determining the compacting behavior of metal powders. This includes compressibility, a key factor in reaching high part density, and green strength, which is a measurement of the mechanical strength of P/M parts in the aspressed condition.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Introduction

ATOMIZATION is the dominant method for producing metal and prealloyed powders from aluminum, brass, iron, low-alloy steels, stainless steels, tool steels, superalloys, titanium alloys, and other alloys. Current atomization technology is the result of steady advances over the last 50 years since the first large-scale production of atomized iron powder during World War II. By the early 1980s atomized powders had accounted for more than 60% by weight of all metal powders produced in North America, with a higher percentage today due to the continued application of prealloyed powders and the diminishing importance of reduced iron powder. Currently, it is estimated that worldwide atomization capacity of metal powders exceeds 10^6 metric tons/year. Atomization has become the dominant mode of powder production because high production rates favor economy of scale and because prealloyed powders can only be produced by atomization.

Atomization is simply the breakup of a liquid into fine droplets. Any material available in liquid form can be atomized. In the case of high melting materials, the result is frozen droplets, that is, a powder. Typically, the size of atomized powders is smaller than $150\text{ }\mu\text{m}$, although larger-sized powders can be produced (in which case atomization is referred to as "shotting" or "granulation"). Atomization is also synonymous with the term nebulization, which is applied to atomization of aerosols in the chemical/pharmaceutical industry.

The general types of atomization processes encompass a number of industrial and research methods. Industrial methods include:

- Two-fluid atomization, where a liquid metal is broken up into droplets by impingement of high-pressure jets of gas, water, or oil (Fig. 1a and b)
- Centrifugal atomization, where a liquid stream is dispersed into droplets by the centrifugal force of a rotating disk, cup, or electrode (Fig. 1c)
- Vacuum or soluble-gas atomization, where a molten metal is supersaturated with a gas that causes atomization of the metal in a vacuum (Fig. 1d)
- Ultrasonic atomization, where a liquid metal film is agitated by ultrasonic vibration (Fig. 1e)

Water, gas, centrifugal, ultrasonic, and soluble-gas atomization are all used in commercial production, but two-fluid atomization methods with gas (including air) or water account for more than 95% of atomization capacity worldwide (Ref 1).

Fig. 1 Atomization process

This article describes the key process variables and production factors for the industrially applied methods of atomization, while briefly mentioning some other methods. It also briefly reviews the effect of atomization methods and process variables on key powder characteristics such as average particle size, particle size distribution or screen analysis, particle shape, chemical composition (including surface composition), and microstructure. These fundamental properties are also discussed in more detail in separate articles in this Volume.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

General Characteristics of Atomized Metal Powders

Particle Size. Atomized metal powders are generally found to follow log normal distributions before any screening is done. In other words, screen analysis data or particle size distributions form straight or nearly straight lines when plotted cumulatively on log-probability paper, as shown in Fig. 2. Two numbers-- d_m median mass diameter and σ_g geometric standard deviation--define the entire size distribution. The geometric standard deviation represents the slope of the curve. It is a measure of the width of the distribution, or the spread of particle size about the median value.

Curve No.	Powder	Mean mass diameter (d_m), μm	Geometric standard deviation (σ_g)
1	Copper, water atomized at 540 bar (by sedigraph)	12.5	2.4
2	Zinc, gas atomized at 20 bar	16	2.1
3	67Pb-37Sn ultrasonically atomized	64	1.31
4	M2 tool steel, water atomized at 140 bar	54	2.13
5	60Pb-40Sn solder, gas atomized at 8 bar	70	2.5
6	Bronze, air atomized at 5 bar	120	2.33
7	Zinc, centrifugally atomized	270	1.4
8	Zinc, water atomized at 55 bar	170	2.58
9	Copper shot, water atomized at 20 bar	280	2.1
10	Phosphor-copper shot, water atomized at 0.5 bar	1950	1.9

Fig. 2 Typical particle size distributions of atomized powders

Standard deviation is obtained as the ratio of the particle size diameters taken at 84.1 and 50.0% of the cumulative weight plot, respectively (Ref 2). A σ_g value of 1.0 signifies that all particles are the same size. Typical σ_g values of water- and gas-atomized metal powders may vary from about 1.7 to 2.3 under good conditions, while bad operation or setup can raise it to as high as 7. Centrifugal and ultrasonic atomization can achieve tighter distributions, as good as 1.3 in some cases (see Fig. 2, line 3 and 7). Vibrating orifice techniques produce almost monosized distributions with σ_g as low as 1.05.

A number of powder particle size distributions are shown in Fig. 2, including gas, water, centrifugal, and ultrasonic. It can be seen that median sizes can range from 10 μm or less in the case of ultrahigh pressure water atomization and some special gas atomizers, to well over 1 mm for very low pressure water granulation. In practical terms, very large particles are normally water quenched because of the huge equipment needed to allow them to freeze in gas. Thus, gas atomizers and most atomizers other than water atomizers are only used for powders finer than about 500 μm .

Particle Shape. The principal characteristics that set atomized powders apart from powder produced by other methods such as electrolysis, reduction, precipitation, and so forth, is their shape and density (Fig. 3). It is generally true to say that atomized powders are free of fine porosity and are relatively compact, with high packing densities and low surface areas, compared with these other types of powder. This means that they have good flow characteristics, good compressibilities, and lower sintering activities than other types.

Fig. 3 Examples of atomized powders. (a) Water-atomized copper. (b) Water-atomized iron, apparent density 2.9 g/cm³. (c) Air atomized aluminum. (d) Helium-atomized aluminum. Courtesy of Huppmann and Dalal

Packing densities range from as high as 65% of solid for spherical powders such as inert gas, ultrasonic, and centrifugally atomized powders frozen in inert gas, to as low as 20% for some alloys prone to oxidation or very rapid freezing in water atomization.

Purity. The concept of purity covers several aspects. It can be defined as an absence of undesirable contaminants. These can be of three types: bulk dissolved impurities, surface impurities, and inclusions (both of nonmetallic particles and of other metals). It is a general characteristic of atomized powders that there are no impurities of the type found in chemically or electrolytically produced powders that can have chloride or sulfate surface contamination. However, dissolved impurities such as oxygen, sulfur, or carbon can be found, normally unchanged in concentration from the melt. Inclusions are also mainly determined by melt practice, except where sloppy handling allows contamination after manufacture, an ever-present problem for all powders. Surface oxidation is often thought of as the main purity index, but is not always as important as the other two types, especially where oxides are readily reduced in sintering. Obviously, inert atmosphere processes minimize contamination, while air atomization introduces the most impurities. Water atomization lies between these extremes.

Gas porosity is a special case of contamination. If porosity is found in any atomized powder, the first suspicion is always of gas solution in the melt, normally hydrogen, but possibly oxygen or steam. Hydrogen-bearing melt stock (e.g., cathode nickel, copper, cobalt) and dampness should be checked and melt deoxidation practice reviewed.

Composition and Microstructure. Atomization has the fundamental advantage over other methods of powder production: the composition is completely flexible, being limited only by melt miscibility or volatility considerations. Thus, tungsten-copper or iron-silver cannot be produced and zinc-titanium is tricky, but a vast range of alloys normally made by casting or forging can be made and even greatly extended due to the rapid freezing rate inherent in atomization. Such materials as brasses, stainless steels, superalloys, NiAl, and so forth, can readily be atomized.

The powder particle sizes resulting from atomization allow cooling rates many orders of magnitude above those in casting processes, ranging from 10^2 to 10^7 K/s. This is now known as rapid solidification (RS), but well before the invention of this terminology, such materials as CuPb bearing alloys and P/M high-speed-steel were being produced by atomization and P/M compaction methods. These alloys remain important to engineering, with outputs of thousands of tons per year, while massive research effort over the last 20 years has led to a rather disappointing level of production of RS products such as amorphous metals and supersaturated solid-solution alloys. Some examples of recent applications that rely on fairly high solidification rates are hypereutectic aluminum-silicon alloys, used in Japan for high-temperature wear resistance in automotive applications, and certain "supermagnets" based on rare earths that have become a billion-dollar business worldwide. Only perhaps 1 to 3% of atomized powders are utilized because of microstructural considerations.

Water Atomization

In terms of tonnage, water atomization is now the preeminent mode of atomization for metal--especially ferrous metal--powders. The largest commercial application of water atomization is iron powder for press-and-sinter applications, and about 60 to 70% of the world's production of iron powder, which now totals some 600,000 to 700,000 metric tons/year, is produced by water atomization. Water atomization is also used for the commercial production of copper, copper alloys, nickel, nickel alloys, stainless steels, tool steels, and soft magnetic powders for pressing and sintering. Water-atomized nickel alloy powders are widely used in thermal spray coating and brazing. Water-atomized precious metals are used in dental amalgams, sintered electrical contacts, and brazing pastes.

As a general criterion, any metal or alloy that does not react violently with water can be water atomized, provided it can be melted and poured satisfactorily. However, it is found in practice that metals melting below about 500 °C give extremely irregular powders due to ultrarapid freezing, which is often undesirable. Thus, zinc is the lowest melting metal produced commercially in this way.

In general, water atomization is less expensive than the other methods of atomization because of the low cost of the medium (water), low energy use for pressurization compared with gas or air, and the very high productivity that can be achieved (up to 30 tons/h or about 500 kg/min). The primary limitations of water atomization are powder purity and particle shape, particularly with more reactive metals and alloys. These generally give irregular powders of (relatively) high oxygen content.

A schematic flow sheet of water atomization is shown in Fig. 4. The major components of a typical installation include a melting facility, an atomizing chamber, water pumping/recycling system, and powder dewatering and drying equipment. Melting of metals follows standard procedures. Air induction melting, arc melting, and fuel heating are suitable procedures.

Fig. 4 Water atomization system. (a) Large-scale (1,000 to 100,000 tons/year) water atomizing system. (b) Key variables in the various stages of the water atomization process

Typically, the molten metal is poured, either directly or by means of a ladle or runner, into a tundish (Fig. 4), which is essentially a reservoir that supplies a uniform and controlled head of molten metal to the tundish nozzle. The nozzle, which is located at the base of the tundish, controls the shape and size of the metal stream and directs it through an atomizing nozzle system in which the metal stream is disintegrated into fine droplets by the high-velocity water jets. The slurry of powder and water is pumped to a first-stage dewatering device (e.g., cyclone, magnetic system, etc.), which often feeds a second-stage (e.g., vacuum filter) dewatering unit to reduce drying energy use.

Atomization

Process Variables

Water atomization involves several variables for the distinct stages of melting, atomization, and particle solidification (Fig. 4b). Many of these variables are interrelated, and each atomization unit is unique to some degree with specific operating conditions. Typical operating conditions range as follows:

- Metal flow (single nozzle), 1 to 500 kg/min
- Water flow rate, 20 to 2000 L/min
- Water velocity (at exit), 10 to 500 m/s
- Water pressure (at exit), 5 to 150 MPa
- Metal superheat, 75 to 150 °C above melting point

Commercial water atomization units typically operate with water flow to metal flow ratios from 2-to-1 to 10-to-1. Operating conditions for specific powders and configurations are listed in Table 1.

Table 1 Operating conditions and properties of various water atomized powders

Alloy	Powder properties ^(a)			Operating parameters ^(a)			
	Median size, μm	Apparent density ^(b) , g/mL	Oxygen, ppm	Metal flow (M), kg/min	Water flow (W), L/min	W/M ratio	Water pressure, MPa
Fe-0.1% C	55	3.2	10,000 ^(c)	150	950	6.3	11
Ag	21	3.4	...	18	100	5.5	50
Fe-0.1% Si	175	3.5	3,400	155	850	5.5	5.8
Fe-15% Si	35	3.6	900	110	250	2.27	25

- (a) All data from V-jet atomizer with 40-50° apex angle, nitrogen purged.
- (b) -250 μm .
- (c) Air purged

In conventional commercial water atomization, the water pressure is usually in the range of 5 to 20 MPa (750 to 3000 psi) resulting in mass median particle sizes of 30 to 150 μm . More specifically, typical molding (100 mesh) powders are normally made using pressures of 7 to 13 MPa (1200 to 2000 psi). However, much higher water pressures (50 to 150 MPa) are used to produce finer powders with median particle size of 5 to 20 μm . This use of high-pressure atomization is driven by the demands of the injection molding and thermal spray industries that require such fine powders.

Water-Jet Nozzle. The nozzles that direct and control the atomizing medium are critical in influencing the efficiency of the disintegration of the liquid metal stream. Many of the nozzle designs are proprietary or described in patent literature (Ref 3). However, nozzle designs in most commercial water atomization units are variants of either V-jet nozzles (Fig. 5a) or annular cone-jet nozzles (Fig. 5b) that are concentric with the metal stream. Annular ring nozzles are utilized in some large-capacity plants making iron powder, but are rarely used elsewhere because they are less flexible

and harder to make than designs based on "V" nozzle configurations with two or more discrete openings located symmetrically about the axis defined by the metal stream.

Fig. 5 Water-jet configuration. (a) Annular jet. (b) Open V-jets. (c) Closed V-jets

The liquid metal stream typically falls a certain distance (typically about 15 to 25 cm) before being hit by the water jets. A partial vacuum is often created above the impingement point of the water, and the gas/air entrained by the water streams can disrupt the liquid metal before it actually meets the water sprays (Ref 4). It should be noted that the water jet that hits the metal stream is typically only a few percent by volume of water droplets, and 98% or so gas.

Another class of water atomizers is used principally at low pressures and for very high flows. This is asymmetrical atomization (Fig. 6), where the melt is poured onto a horizontal jet of water. This is used on a large scale (~ 500 kg/min) for steel and iron shot production and a huge scale (~ 5000 kg/min) for the granulation of blast furnace slags. However, these are millimeter range products and are not discussed here in detail.

Fig. 6 Asymmetric water atomization of slag

Mechanism of Water Atomization. Based on a review of models for various atomization methods (Ref 5), the basic mechanism in water atomization appears based on momentum transfer, where the metal stream is broken up under the impact from water droplets (Fig. 7). Droplet formation by impact rather than shear was first proposed by Grandzol and Tallmadge for water atomization (Ref 6, 7). This model reflects the dispersed nature of the water and an inverse proportionality between particle size and the normal velocity component of the water (with respect to the metal stream axis). Specifically, Grandzol and Tallmadge showed that drop velocity (V_w) is related to the mass median particle size (d_m) such that:

$$d_m = \frac{A}{V_w} = \frac{14,900}{V_w} \left(\frac{1}{n} \right)^{1/3} \quad (\text{Eq 1})$$

where A is a constant, d_m is in μm , V_w is in m/s , and n is the number of metal droplets formed from the impact of one water droplet. In this mathematical form, water flow rate, water pressure, momentum and energy, jet length, and metal flow rate are not primary parameters influencing d_m ; they do, however, affect particle size by influencing water-jet velocities and the number of water droplets. Also, the number of metal droplets produced per water droplet can vary without altering the basic details of the model.

Fig. 7 Impact model of water atomization mechanism. Source: Ref 5

Collisions during atomization can also influence particle size, particle size distributions, and particle shape (Ref 8, 9). Collisions reduce the efficiency of atomization, and the probability of particle collisions increased with increasing metal flow rate. Thus, the maximum of average particle size and geometric standard deviation are achieved in the center of the atomizing stream, where metal concentration generally is highest.

Collisions also cause gas entrapment and microinhomogeneity from internal (primary) particle boundaries. Collisions between particles usually overlap with the earlier stages of atomization. These collisions are minimized or practically eliminated in centrifugal modes of atomization, in which traffic density of the particle decreases rapidly with distance.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Particle Size

In practice, average particle size is controlled by the pressure of the water jets. Higher water pressure directly influences water velocity (V_w), as well as changing the particle size of the water droplets in the jet. These further control particle size, but in a complex and poorly understood way. The relation between d_m and water pressure (P) is shown in Fig. 8 (Ref 10) for various metal powders.

Fig. 8 Particle size of water-atomized metals as a function of atomizing pressure. Source: Ref 10

Based on the straight log-log plots in Fig. 8, the relationship between P and d_m can be expressed as:

$$d_m = KP^m \quad (\text{Eq 2})$$

where K and m are constants for a given material, atomization unit, or nozzle configuration. Variations for two nozzle configurations are shown in Fig. 9 (Ref 11). When d_m is in μm , the parameter m is typically in the range 0.6 to 0.8 for water pressures from 0.1 to 50 MPa.

Fig. 9 Mass median particle size (d_m) versus water pressure for nozzle with V-shaped jets (solid symbols) and conical jets (open symbols). Source: Ref 11

The value of K is also a function of the molten metal or alloy that is being atomized; it is actually a measure of the ease with which a given molten metal stream can be disintegrated. Values of K are almost one order of magnitude higher for aluminum and zinc than for copper and iron-base alloys, meaning that the latter materials require a much lower pressure for atomization. In practice, this means that for two alloys water atomized under identical operating conditions, d_m can vary by a factor of about 6. The value of K is probably determined by the physical and chemical properties of the molten alloy, in particular viscosity and surface tension. Modification of the surface tension by the atmosphere (steam) to allow the formation of oxides is also expected to be important in terms of disintegration of the molten metal stream. Density and thermal conductivity are considered to be of secondary importance in their influence on the magnitude of K .

Other Factors Influencing Particle Size. Besides the velocity of the water jet, particle size after atomization is also influenced by melt superheat temperatures and the apex angle (α) between the jets and metal stream. For water atomization, d_m and σ_g are not particularly sensitive to metal flow rate and the ratio of water flow to metal flow rates. Commercial water atomization units typically operate with water flow-to-metal flow ratios of 5-to-1 to 10-to-1. Experience with water atomization shows that a very low ratio of the water flow-to-metal flow rate (less than 3 to 1) will result in coarser powders. Increasing the water-to-metal ratio above about 6 to 1, however, does not have a significant effect on particle size (Ref 12).

Effect of Superheat. Increasing the melt superheat reduces d_m in water atomization primarily through the effect of temperature on melt viscosity and surface tension. For zinc, an increase in superheat from 100 to 300 °C (180 to 540 °F) reduces d_m from 150 to 100 μm (Ref 10). Similarly, in a cobalt-base alloy, increasing the superheat by about 150 °C resulted in a decrease in d_m of about 13.5% (Ref 13). In addition to its effect on particle size, superheat is used as an operating variable to prevent freezing of the alloy in the exit nozzle of the tundish and to avoid premature freezing of droplets. However, it is very rare to use superheat to control particle size; its effect on particle shape is much more important.

Effect of Apex Angle. Particle size is influenced by the apex angle, as a larger angle increases the velocity component normal to the metal stream. Data reproduced in Fig. 10(a) show that d_m decreases with increasing angle between the axis of the water jet nozzle and the liquid stream. According to Ref 6, this dependence is of the form:

$$d_m \approx \frac{1}{V \sin \alpha} \quad (\text{Eq 3})$$

However, there is a practical limit to the magnitude of the apex angle. Above about 50°, flow of molten metal from the base of the tundish is impaired because of welled-up water, and the incidence of metal freeze-up in the exit nozzle is also found to increase at higher apex angles, especially at higher pressures (Fig. 10). To decrease attenuation in water pressure, a short water-jet length is preferred, but again there are practical limits. It is normally found that using apex angle to control fineness leads to dangerously unstable conditions. It is far better to select a good stable setup with essentially zero

rejection of melt and spray toward the jets and tundish and then provide the necessary pressure to achieve the desired particle size.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Particle Size Distribution

The factors affecting σ_g are somewhat debatable and poorly understood. The data shown in Fig. 11 (Ref 14) might lead to suggestions that very coarse distributions, toward the millimeter range, are tighter (lower σ_g). It is easily argued that extremely low pressures must give tighter distributions as liquid drops cannot be stable in the centimeter range. However, in the author's experience, there is little firm evidence linking σ_g to pressure where particle sizes are in the range from 10 to 200 μm . While it is quite easy to design atomizers with too high an apex angle allowing rejection of the coarse droplets (which can give poor σ_g values up to well over 3.0), it is extremely difficult, indeed practically impossible, to make a jet system that produces a uniformly low value of σ_g below 2.0 for a range of metals.

Alloy and water pressure	σ_g
A Copper atomized at 54 MPa	2.40
B 18Cr-10Ni-2.5Mo stainless steel atomized at 50 MPa	2.40
C Fe-15%Si atomized at 20 MPa	1.70
D M2 high-speed steel atomized at 14 MPa	2.13
E Fe-45%Si for welding electrodes atomized at 4 MPa	1.70
F Zinc for alkaline manganese batteries atomized at 5.5 MPa	2.34
G Copper shot atomized at 2.0 MPa	2.30
H 15% phosphor-copper shot atomized at 0.15 MPa	1.76
I 15% phosphor-copper shot atomized at 0.05 MPa	1.75

Fig. 11 Typical water-atomized particle size distributions. Source: Ref 14

As a general characteristic of water atomization, d_m and σ_g are not particularly sensitive to metal flow rate and the ratio of water flow to metal flow rate. Figure 12 shows that atomization of Fe-15wt%Si powder at rates from 20 to 110 kg/min (stream diameters from 5 to 13 mm) gives very uniform results.

Fig. 12 Effect of metal flow rate on size of water-atomized Fe-15wt%Si powder. Source: Ref 15

The main influence on σ_g , once a good and stable atomizing jet setup is ensured, appears to be melt chemistry. There is no satisfactory explanation of this yet published, but there is no doubt that alloys such as Ni-Cr-B-Si and Fe-Si(15-45 wt%) give consistently narrower distributions ($\sigma_g \sim 1.6-1.8$) than other metals such as copper, nickel, and iron. It can be speculated that this is related to the tendency of such alloys to spherical shape, in turn related to the characteristics of the oxide films formed on the particle surfaces. Those on "self-fluxing" alloys seem to be liquid below the melting point of the alloy and allow it to spheroidize before freezing. As a particle of a given mass can appear on sieving to have various sizes depending on its shape, it may be that a spherical shape, which allows minimum variation in shape and thus reported size, favors low σ_g . However this rationale is largely speculation that requires verification.

Figures 13 and 14 (Ref 16) illustrate the effects of nozzle diameter and pouring temperature for water-atomized copper powders on σ_g and d_m . The large effect of the tank atmosphere--air versus nitrogen (Fig. 13) is interesting. In fact, it is known that if copper is atomized with a large dissolved oxygen content, the powder is much finer (about 30% reduction in d_m at constant pressure). Thus, the large difference between nitrogen and air atmosphere sizes may be due to this effect. Similarly, the chemistry may be directly influencing σ_g . The generally lower values of σ_g at lower metal flow rates reflect the importance of collisions in broadening the distributions.

Fig. 13 Effect of metal-stream diameter on geometric distribution of water atomized copper powder. Pouring temperature 1200 °C (2190 °F); figures in parentheses show average metal flow rates in g/s. Source: Ref 15

Fig. 14 Effect of pouring temperature on distribution of water-atomized copper powder. Metal stream diameter 4 mm (0.16 in.); water flow 320 L/min (85 gal/min); water pressure 13.2 MPa (1915 psi); atmosphere nitrogen. Source: Ref 11

The use of values of σ_g , in combination with median particle size according to Fig. 11, permits the estimation of powder yields as a function of atomizing pressure. Where particles are needed in a narrow size range, for example, $-150+53 \mu m$, the impact of σ_g on yields is very important (see Fig. 15).

Fig. 15 Master yield curve showing yield between two sizes as a function of size ratio and standard deviation (σ_g)

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Powder Characteristics

Water atomized powders generally are quite irregular in shape compared to gas atomized powders and have relatively higher surface oxygen contents (depending on the alloy reactivity). Gas atomized powders, on the other hand, generally are more spherical or rounded in shape and, if atomized by an inert gas, generally have lower oxygen (oxide) contents. There are, of course, exceptions in each type. For high-volume, low-cost production, water atomization generally is

preferred over gas atomization, providing powder characteristics are compatible with the application. Typical characteristics of various water atomized powders are summarized in Table 2. Factors affecting powder characteristics are summarized in Table 3 (Ref 17).

- (a) Note: A plus sign indicates that there is some direct relationship between the powder property and the atomization parameter, while a minus sign signifies some inverse relationship. Zeroes (0) indicate the absence of a strong relationship or that data are conflicting.

Particle Shape. The irregular shape of water atomized powders is attributed by some authors (Ref 10, 18) to the relative rates of cooling and spheroidizing of liquid droplets. For example, if the spheroidization time (τ_{sph}) of the liquid droplet is short compared to its solidification time (τ_{sol}), particle shape tends to be spherical; if spheroidization time is long, particles tend to be irregular. Thus, water atomized powders tend to be more irregular because cooling rates for water atomization are one to two orders of magnitude larger than for gas (nitrogen or argon) atomization. The particle shape of water atomized powder also becomes more irregular if small amounts of impurities lower surface tension and thus increase spheroidization time.

Figure 16 (Ref 10) compares solidification times for 100 μm particles of different melting point metals with the apparent densities of water atomized powders as a percentage of solid. It can be seen that metals melting above about 500 °C have long freezing times. This is due to the steam film formed at such temperatures. By contrast, metals such as tin, lead, and zinc freeze very fast due to nucleate boiling heat transfer, unimpeded by steam films. However, a fusible alloy has so little thermal head that it cools slowly. The density data mirror the resulting curve. It should be noted that none of the metals showing high densities has a major affinity for oxygen and that such alloys as stainless steel show densities of only about 30%.

(a)

(b)

Fig. 16 Freezing time and relative density of powders as a function of melting point. (a) Freezing time of 100 μ m particles versus melting point. (b) Relative apparent density of water-atomized powders versus melt points. Source: Ref 10

Oxidation. During water atomization, most metals react with water or steam to form oxides, following a chemical reaction of the form: $x\text{Me} + y\text{H}_2\text{O} = \text{Me}_x\text{O}_y + y\text{H}_2$. Oxidation generally increases with increasing superheat of the liquid metal and depends on particle size. Some materials exhibit a minimum if oxygen content is plotted versus particle size. Such a minimum may result from two opposing factors. With increasing particle size, cooling time, and exposure to oxidation increase, oxide layers become thicker. Conversely, with decreasing particle size, the specific surface area of a powder increases rapidly.

In addition to the amount of oxidation, the nature and composition of oxides and their spatial distribution within a particle can have a great effect on the usefulness and subsequent processing requirements of a powder. Surface analytical techniques have shown that the surfaces of water atomized alloys are typically highly enriched in the oxides of elements that have high negative free energies of oxide formation and high diffusivities at elevated temperature. Oxide films have thicknesses ranging from tens to thousands of nanometers.

This phenomenon is also true for gas atomized powders in which some oxidation has occurred during atomization. Typical oxygen contents of water atomized metal powder are:

Metal	Oxygen content, ppm
Silver	100
Gold-nickel	<100
Copper	<800
Copper-tin	<400
Nickel	<500
Iron	1,000-3,000
Cobalt	2,000-3,000
Iron-carbon	500
Aluminum	2,000
Fe-13Cr	1,000-3,000

Within the group of alloys that contain elements with intermediate oxygen affinity (chromium, manganese, and silicon), silicon-containing alloys generally produce low-oxygen-content powders, while manganese-containing alloys become heavily oxidized during water atomization. This tendency is attributed to the more protective nature of silicon oxide films compared to manganese oxide films. Figure 17 shows this effect for 304L stainless steel.

Fig. 17 Effect of silicon and manganese content on the oxygen content of 304L powders

Oil Atomization

Atomization of metal has been done commercially with oil, which should avoid the problem of powder oxidation (Ref 1). Commercial application is limited to production of relatively high-carbon (0.4 wt% C) steel as an inoculant in continuous casting of steel. Oil-atomized powders resembled water-atomized powder with d_m typically at 70 μm and sometimes down to 30 μm . Oil-atomized powders have densities intermediate between water- and gas-atomized powders as the quench rate is slower and oxidation much less. However, carbon pickup occurs to an extent depending on metal temperature and carbide-forming tendency (Ref 19).

Gas Atomization

Gas atomization is the process where the liquid metal is disrupted by a high-velocity gas such as air, nitrogen, argon, or helium. Atomization occurs by kinetic energy transfer from the atomizing medium to the metal.

Gas atomization differs from water atomization in many respects. Rather than being dominated by the pressure of the medium like water atomization, it is found that the gas-to-metal ratio is the dominant factor in controlling particle size, with median particle size being related inversely to the square root of the gas-to-metal ratio. The reasons for this fundamental difference are easily explained. In the case of gases, increases in pressure above 0.1 MPa (the pressure at which sonic velocity is reached) give only very small increments in gas velocity. In contrast, to reach sonic velocity (in air/nitrogen) with a water jet, a pressure of nearly 40 MPa is needed and the velocity increases uniformly as the square root of the pressure. Also, gas atomization takes place by the action of a continuum on another, while in water atomization a stream of droplets (in an entrained gas flow) acts on a continuum. The density of the water medium is about a thousand times higher than typical gases, giving much greater "punch" or short-range forces.

Gas-atomizing units also come in a much wider range of designs than water atomizers and are classified as either "confined" or "free-fall" nozzle configurations (Fig. 18). There is also a third type, "internal mixing," where the gas and metal are mixed together before expanding into the atomizing chamber (discussed in the following sections). Free-fall gas units are very similar in design to water-atomizing units. However, due to the rapid velocity decay as the gas moves away from the jet, in free-fall gas units it is very difficult to bring mean diameter of powder below 50 to 60 μm on iron-base material. High efficiency is thus difficult to obtain in free-fall systems, although special design and configuration of nozzle arrangements can produce relatively fine powder at reasonable gas-to-metal ratios for high-velocity oxyfuel thermal spray, plasma tungsten arc (PTA) welding, and hot isostatic pressing applications. As well as vertical designs, resembling water atomizing designs, there are a number of asymmetric horizontal designs where a vertical, inclined, or sometimes horizontal melt stream is atomized by essentially horizontal gas jets. These designs are widely used in zinc, aluminum, and copper alloy air atomizers.

Fig. 18 Two-fluid atomization with (a) free-fall design (gas or water) and (b) continued nozzle design (gas only). Design characteristics: α , angle formed by free-falling molten metal and atomizing medium; A , distance between molten metal and nozzle; D , diameter of confined molten metal nozzle; P , protrusion length of metal nozzle

Closed or "confined" nozzle designs enhance the yield of fine powder particles ($\sim 10 \mu\text{m}$) by maximizing gas velocity and density on contact with the metal. However, although confined designs are more efficient, they can be prone to freezing of the molten metal at the end of the tundish nozzle, which rapidly blocks the nozzle. Also, the interaction of the gas stream with the nozzle tip can generate either suction or positive pressure, varying from suction that can triple metal flow rate to back pressure sufficient to stop it and blow gas back into the tundish. Thus, great care is needed in setting up close-coupled nozzles, and the closer the coupling, the greater the care (as well as the efficiency). Water-bench test techniques (Ref 20), where the melt is substituted by water as a model liquid, have allowed consistent hot performance to be achieved by cold testing. Tests of suction alone have proved poor predictors of hot performance because the gas stream is considerably affected by its interaction with the liquid being atomized.

Confined designs are of two types: conventional (Fig. 18) or ultrasonic (Fig. 19). The ultrasonic design uses the Hartman tube principle to apply high-frequency pulsation to the gas stream, with gas exit velocities reported to be Mach 2 to 2.5 and the major pulsation frequency at about 100,000 Hz.

Fig. 19 Ultrasonic gas atomizer (U.S. patent 2,997,245)

In many confined designs, the circulation created by the gas flowing down the side of the tundish nozzle causes the molten metal to flow across the face of the ceramic nozzle to its edge, where it is sheared by the flowing gas (Ref 21, 22, 23). These nozzles are referred to as "prefilming" and are quite widely used (see Fig. 20).

Fig. 20 Prefilming operation for gas atomization. (a) The prefilming operation of a closed nozzle. (b) The atomization of aluminum powder ($25\ \mu\text{m}$). Source: Ref 22, 23

Worldwide annual tonnage of inert gas-atomized powder is much less than that of water-atomized powders, probably amounting to no more than 50,000 tons/year. Metal feed rates are lower than in water atomization, and melt size is smaller. However tonnage of air-atomized powders, especially zinc and aluminum, but also tin, lead, and copper alloys, probably exceeds 300,000 tons/year. Most of these air atomizers operate continuously for many hours or even days. Multinozzle units are often used to boost output on aluminum and zinc.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Process Variables

Conventional atomization pressures are typically in the range 0.5 to 4 MPa (70 to 600 psi), and gas velocities in the nozzles range from Mach 1 to 3. However, in free-fall atomizers, measured gas velocities in the impingement area normally have fallen to 50 to 150 m/s (for air/nitrogen). Typically, gas-atomized powder is spherical with a log normal size distribution. Mean particle size is usually in the range 10 to 300 μm with a standard deviation of about 2. Oxygen content is about 100 ppm. Powder cost is extremely sensitive to the economies of scale. Prealloyed ferrous, nonferrous, and specialty alloys are made by inert gas atomization.

For free-fall gas atomization, the key process variables are similar to those of water atomization (Fig. 4b). In a confined-nozzle design, the major parameters are the geometry of the tundish nozzle tip, the gas jet apex angle, and gas jet diameter (or width for an annular design), the number of jets, and the horizontal spacing between the jets and the tundish nozzle center line.

In conventional gas or air atomization, typical metal flow rates through single orifice nozzles range from about 1 to 90 kg/min (2 to 200 lb/min). Typical gas flow rate ranges from 1 to 50 m³/min (40 to 1600 ft³/min) at gas pressures in the range of 350 kPa to 4 MPa (50 to 600 psi). Effective gas velocities are very difficult to measure and depend on nozzle design, ranging from 20 m/s (66 ft/s) to supersonic velocities. The temperature differential between the melting point of the metal and the temperature at which the molten metal is atomized (superheat of the molten metal) is generally about 75 to 150 °C (135 to 270 °F). In gas atomization with argon or helium, the cost of gas consumption is significant, and a means of circulation to facilitate gas reuse is desirable in larger-scale facilities.

In practice, for a given gas nozzle design and size, average particle size is controlled by the pressure of the atomizing medium and the melt flow rate (controlled by nozzle diameter and nozzle suction). For all nozzles, the velocity of the gas usually "chokes" at sonic velocity (about 300 m/s, or 1000 ft/s, for nitrogen and argon) in the narrowest region of the nozzle if the upstream gas pressure is at least 1.9 times the external pressure.

Consequently, the amount of gas flow (A) depends on gas pressure, temperature, and nozzle area. For ideal conditions and zero velocity on the entrance side of the nozzle, gas flow is:

$$A = a \left(\frac{2}{k+1} \right)^{k+1/2(k-1)} \frac{p\sqrt{2g}}{\sqrt{RT}} \quad (\text{Eq 4})$$

where a is the cross section of gas nozzle at exit, k equals C_p/C_v , the ratio of specific heat at constant pressure and volume, p is the gas pressure in gas reservoir, T is the temperature in gas reservoir, R is the gas constant, and g is the acceleration due to gravity. For nitrogen, with $k = 1.4$:

$$A \approx 4 \times 10^6 \frac{ap}{\sqrt{T}} \text{ g/s} \quad (\text{Eq 5})$$

As a compressible fluid passes through a nozzle, a drop in pressure and a simultaneous increase in velocity result. If the pressure drops sufficiently, a point is reached where, in order to accommodate the increased volume due to expansion, the nozzle unit must diverge. Thus, nozzles for supersonic velocities must converge to a minimum section and diverge again.

Gas efficiency can be compared on the basis of how much powder surface is generated per unit volume of gas spent. This criterion accounts for higher gas consumption requirements when higher gas pressures are applied in producing finer powders. Confined- or "close-coupled-" nozzle designs give higher efficiencies at comparable gas/metal ratios (Fig. 21) (Ref 24). A more simple method is to use the equation:

$$d_m = k/\sqrt{G/M} \quad (\text{Eq 6})$$

Where k is a constant for the process and metal, and G/M is the gas/metal ratio, which is variously measured in kg/kg or cubic meters of gas per metal mass (m^3/kg). A typical plot of d_m versus G/M is shown in Fig. 22 with data from several published papers. For a given metal, the value of k can be taken as an index of efficiency in terms of fineness achieved per unit gas consumed (a lower value of k is a higher efficiency). If d_m is in microns (μm), k is the median size when using one cubic meter of gas per kilogram of metal, a not untypical level.

Fig. 21 Gas efficiency expressed as powder area produced per unit volume of gas consumption (m^2/m^3). Source: Ref 24

Fig. 22 Effect of gas-to-metal ratio on median particle size. Source: Ref 14

Typical values of k shown in Fig. 22 range from 40 to 60 μm for close-coupled gas nozzles.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Models of Gas Atomization

The basic conceptual mechanism of droplet formation in gas atomization is a three-step process first proposed by Dombrowski and Johns (Ref 25). Figure 23 shows this model for the disintegration of a liquid sheet by a high-velocity jet of gas. The initiation of sinuous waves, or other disturbances that rapidly increase in amplitude in stage I (see the following paragraphs), is followed by fragmentation, which forms ligaments in stage II. Breakdown of ligaments into droplets occurs in stage III. Thus, there are three stages involved in the atomization process: formation of wave with a particular wavelength λ and wave number k (i.e., $2\pi/\lambda$), removal of the ligament, and spheroidization of the ligament.

Fig. 23 Model for the disintegration of a liquid sheet by a high-velocity gas jet. Source: Ref 25

Bradley (Ref 26, 27) developed a detailed mathematical model of the first two stages and invoked Rayleigh instability for the final stage. In the first stage of the atomization process, it is necessary to determine the wave number k_{\max} with the fastest growing amplitude. In the second stage of atomization, Bradley suggested that the ligament diameter D is related to the wavelength λ_{\max} (i.e., $2\pi/k_{\max}$) by a linear equation:

$$D = \epsilon \lambda_{\max} = 2\pi\epsilon/k_{\max} \quad (\text{Eq 7})$$

where the parameter ϵ (of the order of 0.25) was determined in earlier studies on the air atomization of water.

In the third stage, the cylindrical ligament of diameter D breaks up by Rayleigh instability into a series of spherical droplets of diameter d such that:

$$d = D/0.53 \quad (\text{Eq 8})$$

From the above two equations, the predicted droplet diameter d (and hence the powder particle diameter) is given by:

$$d = 11.86\varepsilon/k_{\max} \quad (\text{Eq 9})$$

Bradley (Ref 26) also gave a graphical method of evaluating the droplet diameter for Mach numbers (M) between 0.1 and 0.9. This was in terms of a dimensionless parameter L defined as:

$$L = k_{\max} \gamma / \rho_g U_s^2 \quad (\text{Eq 10})$$

where γ is the liquid/gas interfacial energy that opposes the growth of the wave, ρ_g is gas density, and U_s is the sonic velocity of the gas. The relation for L comes from a dimensional analysis that suggests a negligible effect of liquid metal viscosity on the wave development, at least in determining k_{\max} . The resultant droplet diameter d is then given by:

$$d = 2.95\gamma / L\rho_g U_s^2 \quad (\text{Eq 11})$$

For all practical purposes, L is a function of Mach numbers (M); a plot of the dimensionless quantity L against M is given in Fig. 24. This is a universal curve for the atomization of liquid metals. Knowing the value of M during gas atomization, L is obtained from Fig. 24. Substitution of this value of L in Eq 11 gives the predicted liquid droplet diameter D . Unfortunately, predicting or measuring M is practically impossible as it varies very rapidly in space and atomization does not take place instantaneously at a point.

Fig. 24 Universal curve of L against M . Source: Ref 2

Bradley's model has been shown to be accurate within a factor of two with some experimental data (Ref 1). However, there are some obvious limitations. As presently constructed, Bradley's model does not give any indication of the origin of the spread in particle sizes produced by gas atomization. This phenomenon clearly needs to be included in a comprehensive model of the process. There are also observations reported by See and Johnston (Ref 28) that need to be explained. One observation, revealed by high-speed photography, is that under impact of the gas stream a hollow "cone" of metal is formed that breaks up and then the whole process repeats itself. If the Bradley model is valid, then this cone has to be the fastest growing wave of the Bradley analysis. It is not immediately obvious why the process is cyclic rather than continuous. The work of Miller observing the process also shows marked instabilities on a 10 to 100 ms scale. (Ref 29).

Particle Size Prediction with Adjustable Parameters. Bradley's model does not require the use of any adjustable parameter because ε was determined from Bradley's earlier studies on the air atomization of water. However, another approach based on impact force and work (Ref 30) can be used to predict particle size from gas atomization. This method is based on the following expression (which was originally derived for centrifugal atomization, Ref 31):

$$d = \sqrt{\frac{6 \cdot \sigma}{\rho_m \cdot a}} \quad (\text{Eq 12})$$

where σ is surface tension, ρ_m is the alloy density, and a is acceleration associated with the particular gas/metal interaction. From an analysis of the basic variables for inert-gas atomization (Ref 30), Eq 12 expands into the form:

$$d = \sqrt{\frac{A \cdot \sigma}{\rho_m \frac{M_g}{M_m} \cdot V_g (1 - B \eta D)}} \quad (\text{Eq 13})$$

where η is the dynamic viscosity of the metal (in $N \cdot s/m^2$), V_g is the velocity of the gas leaving the nozzles, D is the diameter of the metal stream, and M_g and M_m are mass flow rates of the gas and metal, respectively.

Constants A and B in Eq 13 are system constants that need to be defined for the individual atomization system in order to enable use of the model. By plotting results from atomization runs with different values of the parameters the constants A and B can be estimated and the system thereby characterized. This model has been used in two atomization plants to further develop gas atomization processes, and it accurately predicts experimental results (Ref 30). It is noteworthy that it has the same functional relationship as Eq 6.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Gas-Atomized Powders

Particle Size and Size Distribution. Gas-atomized powders generally have a log normal size distribution, where the standard deviation σ is normally around 2.0 ± 0.3 . Lower values are associated with very small metal flow rates, and thus, perhaps falsely, with fine particle sizes (which result from low metal flow rates and constant gas flow rates). Data from Unal (Ref 32) are shown in Fig. 25. Particle size is controlled by changes in gas-to-metal flow ratio.

Fig. 25 Variation of geometric standard deviation (σ_g) with metal flow rates. Source: Ref 32

By comparing the literature on gas-atomized metal powders and by using a relationship developed by Wigg (Ref 33), Lubanska (Ref 34) proposed the following empirical equation for the average particle size (d_m) of gas-atomized powder:

$$\frac{d_m}{d_{Met Str}} = K \left[\frac{v_m}{v_g} \frac{1}{W} \left(1 + \frac{M}{A} \right) \right]^{1/2} \quad (\text{Eq 14})$$

where W is the Weber number ($W = \rho V^2 d_{Met Str} / \sigma$), d_m is the mass median particle diameter, $d_{Met Str}$ is the diameter of metal stream; v_m is the kinematic viscosity of liquid metal, v_g is the kinematic viscosity of atomizing medium, V is the velocity of atomizing medium, ρ is the density of the gas, σ is the surface tension of liquid metal, M is the mass flow rate of liquid metal, A is the mass flow rate of atomizing medium, and K is a constant.

The individual terms of this equation are dimensionless; the Weber number measures the ratio of inertial to surface tension forces. Within the explicit form for the Weber number, particle size decreases with decreasing surface tension of the liquid metal and with increasing velocity of the atomizing medium.

Data from Ref 34 for various metals are depicted graphically in Fig. 26. The log/log scale obscures an order of magnitude scatter band, and attempts to apply the 1968 Lubanska correlation to practical nozzle systems have been fruitless. Many of the parameters in it are there simply to provide dimensionless elegance and are based on no experimental data whatever. As in the case of Bradley's Eq 13, the inclusion of a velocity term, when the velocity field is extremely complex and variable, nullifies any attempt at prediction, as predicting the velocity is as difficult as predicting the particle size. Thus, more recent practical workers in the field have tended to leave detailed process modeling, even with high-powered computational fluid dynamic (CFD) techniques, to academics and to use either simple empirical correlations such as Eq 6 or advanced observational techniques to understand the process. The CFD techniques have been used to predict gas flow patterns with some success, but modeling the interaction of the gas flow with the metal, and the effect of the metal on the gas flow-involving both intensive momentum and heat transfer (the latter alters both the volume and physical properties of the gas)--has proved beyond the most powerful computers, and the observed fact that atomization is essentially a nonsteady state process (Ref 29) makes it extremely doubtful that any satisfactory solution is possible in the foreseeable future.

Fig. 26 Correlation of atomization data for liquid metals. See Eq 14 in text for line equation. Source: Ref 34

Various other empirical equations are given in the Selected References at the end of this article. Some of these empirical relationships can be rationalized in terms of physical models for droplet formation. The so-called maximum stability criterion, for instance, gives maximum drop size as a function of surface tension of the liquid metal (σ), gas density (ρ_g) and velocity (V) of the atomizing medium as:

$$d_{crit} \approx \frac{\sigma}{\rho_g V^2} \quad (\text{Eq 15})$$

This equation applies to the breakup of ligaments (Ref 28). Secondary disintegration into particles smaller than d_{crit} occurs only if the dynamic pressure due to the gas stream velocity exceeds the restoring force of surface tension. Due primarily to the higher surface tensions of liquid metals, energy requirements and, therefore, gas pressures used for atomizing metals are generally higher than for other liquids--typically between 350 and 2750 kPa (50 and 400 psi).

Powder Cleanliness. Impurity control is of paramount importance for high-performance applications. Currently, inert gas atomization systems have been perfected so that the oxygen content of a powder does not significantly exceed that of the liquid metal prior to atomization. To minimize the presence of oxides in the molten metal prior to atomization, particularly in the case of alloys containing readily oxidizable elements, good melting and deoxidation practices are important. Precautions during transfer of the liquid metal from ladle to tundish and avoidance of turbulence inside the tundish are equally important. In the case of the most critical superalloys, recent workers have developed a bottom-pouring electroslog remelting furnace that discharges using a ceramic-free pouring nozzle to minimize all possibility of inclusion pickup (Ref 35).

Gas-atomized metal powders may contain small amounts of the atomizing gas within individual particles, which can cause microporosity, especially in the case of argon. This gas probably originates from mechanical entrapment that occurs when particles collide during atomization. Porosity can also originate from hydrogen dissolved in the melt. In practical terms, porosity in atomized particles is found mostly in the coarser particles. Thus, trends to screen finer to reduce the maximum possible inclusion size have helped to reduce this problem. In the case of high-speed steels, severe porosity on

heat treatment was eliminated by changing from inert, insoluble argon to reactive, soluble nitrogen, which merely incorporated itself into the carbides.

Particle Shape. The surface of (inert) gas-atomized powders is ideally smooth and spherical. However, in practice, especially when finer powders are produced, "satelliting" is seen (see Fig. 3e). This is the decoration of the larger particles by attached smaller particles. This is believed to be caused by the circulation of gas within the atomizing chamber that lifts finer particles back into the spray plume, where they collide with larger, still partly molten particles. It is found that this problem is much less severe when water quench sprays are used, which scrub out the fines and also that it gets much worse as finer median sizes are produced.

The spherical shape and generally smooth surfaces of gas-atomized powders limit the development of green strength in cold compaction. In addition, prealloying before atomization increases particle hardness and strength, which reduces compressibility. These intrinsic limitations in gas-atomized powders have stimulated development of elevated-temperature consolidation processes to achieve high density; examples include hot extrusion and hot isostatic pressing. However, spherical particles have ideal flow characteristics and are desirable for feeding to thermal spray processes.

The far larger volumes of air-atomized powders do not all suffer from the drawback of high sphericity, as can be seen in Fig. 3(c), which shows air-atomized aluminum powder with a characteristic shape caused by a strong oxide film. Zinc, aluminum, and copper-zinc (brasses) are similar to this and can be cold compacted. However, if the oxide-forming tendencies are minimal, for example in phosphorous deoxidized copper or bronze, good spheres can result, such as filter grades of 10% Sn bronze.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Other Gas Atomization Methods

Ultrasonic gas atomization (Fig. 1e and 19) is claimed to allow finer particles, but no published comparative work has clearly demonstrated significant advantage over similar close-coupled nozzles. No commercial operator is known to use the method, and the largest melter used has been in the 10 to 50 kg size range.

Internal Mixing Nozzles. Typical values of k in Eq 6 shown in Fig. 22 range from 40 to 60 μm for close-coupled gas nozzles. Far higher efficiencies are obtained in another type of nozzle, the internal mixing nozzle, where gas-to-metal ratios are of a totally different order of magnitude than in conventional gas atomization (Fig. 21). In an internal mixing atomizer, gas and metal are mixed under pressure, and expansion and atomization take place at the nozzle exit into the atomization chamber. Two such processes are used today for the production of superalloy powders on a commercial scale (Ref 24). The first of the two gas/mix processes is known as vacuum atomization (Fig. 1d), where dissolved gas in the

liquid metal adds an extra atmosphere pressure difference in the beginning of the atomization to promote the expansion of the gas in solution in the metal. In addition to the dissolved gas, some gas is also added to the system to finally break up the liquid into fine droplets as the dissolved gas alone would not be sufficient to create the fine particles that can be achieved with this process.

The vacuum atomization process is only operated by one company and is highly proprietary. The lack of any other operators, even when the original patents have expired, may indicate that the rather complex plant may be too expensive to justify the gas savings.

In another type of internal mixing nozzle (Ref 36), very high efficiency was achieved (Fig. 27), but low outputs. The k value in Eq 6 was below 10. The fundamental drawback of the internal mixing concept is the engineering difficulty of arranging to pressurize the melt to the same pressure as the gas. There are also problems with erosion of the ceramic nozzles employed as the metal velocity, normally only 1 to 3 m/s in a pouring nozzle, could be expected to rise to the same order of magnitude as the gas velocities, that is, perhaps to 100 m/s. Thus, applications are so far very limited indeed.

Centrifugal Atomization Methods

In centrifugal atomization, centrifugal force breaks up the liquid and throws off the molten metal as a spray of droplets that then solidify as powder particles. As shown in Fig. 1, there are several different types, which are discussed. In

general, centrifugal atomization methods are far more energy efficient than gas and water atomization, where only about 1% of the jet energy is used in the disintegration of the metal stream (Ref 1). In contrast, the energy used in centrifugal methods is low as all the rotational work directly accelerates the metal droplets, instead of the atomizing medium, as in the case of two-fluid techniques. Centrifugal atomization also generally leads to a much narrower spread in particle sizes than does gas atomization (see Fig. 2), with σ_g as low as 1.2 to 1.4 in some cases.

As the process depends on the solution to the problem of finding a compatible material for the spinning disk or cup, the applications that have been, and are currently, used on a significant industrial scale are quite distinct. They are reviewed in order of ascending melting point of alloy.

Spinning Disk Atomization of Electronic Grade Solder. Solder powder for electronic applications has a very demanding specification; it must be perfectly spherical and satellite-free, it must be very low in oxygen content (~ 100 ppm), and it must have a very narrow size distribution. In 1997, more than half of the demand was for type III size grade that is nominally $-45+25 \mu\text{m}$, and often demanded as $-40+30 \mu\text{m}$. Attempts to make this product with inert gas atomization have now virtually ceased as yields are as little as 5% and the avoidance of satellites is very difficult.

In the United States, Japan, and Europe, there are many producers using spinning disk methods to make this product. This is possible because a steel disk is well wetted by normal Sn63Pb37 solder and is not eroded very fast. A disk with diameter of 40 to 100 mm running at speeds of 30,000 to 60,000 rpm can produce this material with good yields of 30 to 70% and at (gross) rates of 50 to 100 kg/h. The plant is only about 2 to 3 m in diameter and inert gas filled. Unfortunately, a small amount of ultrafine particles is produced as a secondary peak in the distribution, and some problems with satellites are found. Annual production, if the modest yields are taken into account, is probably currently several thousand tons per year.

Spinning-Cup Atomization of Zinc, Aluminum, and Magnesium. When used on higher-melting metals, it is difficult to run at the sort of speeds that are used on solder. However, there are markets for coarser powders of zinc (alkaline batteries), aluminum (chemical), and magnesium (flares) that have made this a significant process. In all cases, the cup is 100 to 200 mm diameter, running at moderately high speeds, from 3,000 to 10,000 rpm. The vessel size needed is very large, up to 12 m in diameter, but productivity can be very high. In the case of zinc for battery applications, which is commonly required as $-600+100 \mu\text{m}$ material, air atomization may give yields of 70 to 80%. Using a 5 kW spinning cup, 98% can be achieved, at outputs of several tons per hour, and with no compressor costs (an equivalent air atomizer might use several hundred kilowatts of compressed air). However, large output is needed to justify the large-scaled plant needed. Many thousands of tons per year are made in this way.

Aluminum is also processed in this way, but because of the large size of plant needed to freeze coarse particles, it is done in open air, which produces needles (see Fig. 3d). In this case, a perforated steel or cast iron cup is used to make a series of streams of metal, which break up into needles due to the oxide film on them. Production is considerable, probably thousands of tons per year.

Magnesium powder for flares was made in several similar systems in the United States during the Vietnam war at rates of 1 ton/h. Excellent yields of a powder almost free of the very dangerous $-100 \mu\text{m}$ fines were obtained. In this case, the fact that liquid magnesium does not attack iron simplified cup manufacture. Due to lack of current demand, this production process is seldom used.

The rapid solidification rate (RSR) process, which was first developed in the 1970s by Pratt and Whitney for making superalloy powders, is another form of centrifugal atomization. To overcome the problems of the material in handling high melting and aggressive alloys, the process employs a high-speed water-cooled rotating disk (20,000 to 30,000 rpm), which breaks up the molten metal stream. To enhance solidification rates, the resulting droplets are then hit by high-pressure helium gas as they leave the periphery of the rotating disk. The RSR powders are spherical, with an average particle diameter $<100 \mu\text{m}$. High cooling rates ($>10^5 \text{ }^\circ\text{C/s}$) are achieved in the small powder particles, and this leads to a high degree of compositional homogeneity and fine-scale microstructure. An early plant of this type is shown in Fig. 28.

Fig. 28 Schematic of first-generation RSR machine. The second-generation machine incorporates closed-loop helium recirculation, higher atomization speeds, and a three-fold increase in melt capacity. The third-generation machine retains these features, but the melt capacity is increased to 900 kg (2000 lb).

The first RSR unit was operated in late 1975, producing IN-100 powder as a model, and patents were issued in 1978 (Ref 37) and 1982 (Ref 38). In addition to superalloys, the process has been used to produce specialty aluminum alloy, beryllium alloy, molybdenum, titanium alloy, and silicide powders. The RSR powders currently produced by Pratt and Whitney are nickel-base superalloys, steels, and aluminum alloys. These alloy types are induction melted in vacuum. In a more recent development of the RSR process, reactive metals (titanium, molybdenum) and silicides have been arc melted prior to atomization. For titanium alloys, melt sizes up to 45 kg have been atomized successfully.

For nickel-base alloys, representative operating conditions are disk rotation speed 2500 radians/s, melt flow rate 0.2 kg/s, gas (helium) velocity 170 m/s, gas mass flow rate 1 kg/s, helium backfill partial pressure 33 kPa, and melt superheat 100 °C (180 °F). A major consideration in the design of this rotating disk atomizer was the desire to achieve extremely high cooling rates in the droplets by convective cooling in the helium gas. Depending on the diameter of the rotating disk, droplets are ejected at velocities in the range 40 to 110 m/s. Typically RSR droplets smaller than 100 μm diameter cool at rates of about 10^5 °C/s.

This technique produces notably narrow distributions and is used commercially to make plasma spraying powders where size ranges such as -150+53 or -100+38 μm may be needed. However, the uncontrolled geometry of the skull on the rotating disk, and the problems of out-of-balance forces, degrades the size distribution significantly compared with that achieved with lower-melting materials where the cup or disk has precise geometry. It also results in heavy maintenance costs on the spinning-cup assembly. As the melting process is normally batched, this is a major drawback. Lower-melting materials are easily supplied continuously, avoiding or minimizing startup and maintenance problems. As a result of these

disadvantages, gas atomization has continued to dominate the production of higher-melting alloy powders. The use of huge volumes of costly helium is another drawback, and the benefits of the rapidly solidified microstructures have yet to find major commercial paybacks outside the aerospace sector. Thus, Pratt & Whitney remains the only operator in the 1990s, and the few attempts that have been made to develop similar devices elsewhere have not been productive. Production is probably less than 1000 tons/year.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Rotating Electrode Process

The rotating electrode process (REP) is a commercial form of centrifugal atomization that overcomes the material problem by spinning the metal before it is melted. Thus, the spinning element is a consumable electrode. Material in the form of a rod electrode is rotated at about 15,000 rpm while it is melted by an arc. The molten metal is ejected centrifugally in the form of molten-metal droplets that solidify before hitting the walls of the inert-gas-filled chamber. The REP concept was developed by Nuclear Metals, Inc., and resulted in the granting of patents (Ref 39).

Figure 29(a) shows the process carried out using a plasma torch process (PREP). The original method (REP) used a tungsten-tipped cathode as shown in Fig. 29(b). Use of a transferred arc helium plasma torch eliminates the tungsten contamination characteristic of the earlier design. This was a critical factor in titanium powder production.

(a)

(b)

Fig. 29 Schematic of the REP. (a) Plasma arc rotating electrode process (PREP). (b) Tungsten tip rotating electrode process (REP)

The rotating electrode and plasma rotating electrode processes offer certain advantages over other powder-making processes. Titanium alloys are optimally produced by these methods, because the corrosive nature of molten titanium and the difficulty involved in containing this molten material are overcome. Generally, many high-duty materials to be made into powder benefit in that there is no liquid metal/container contact. This ensures that ceramic particles are not inadvertently added. When the addition of foreign particles from external sources is prevented, these processes provide a method for making powders to exact standards of cleanliness. However the bar stock must first be sufficiently clean itself.

As with other centrifugal methods, size distributions can be held within tighter ranges than is commonly achieved by gas atomization. A cumulative plot of weights passing through progressively finer screens versus screen size is shown in Fig. 30. The effect of rotation speed is illustrated, and the median particle size d_{50} is approximately defined by:

$$d_{50} = \frac{K}{\omega\sqrt{D}} \quad (\text{Eq 16})$$

where ω is the rotation rate, D is the diameter of the electrode, and K is a constant for a given alloy for a limited range of arc power. Hollow gas-filled particles, which cause thermally induced porosity in compacts, are not generated. Powders made by these techniques have demonstrated a high degree of sphericity along with good surface quality. Particles also pour readily into molds of complex shape. They give consistent packing at approximately 65% full density so that near-net shapes can be obtained by HIP. However, a major drawback is the mechanical limitations on rotational speed, which limit the minimum median particle size to about 50 to 150 μm (depending on alloy density, etc.). Also, the cost of making a high-quality bar of metal is very significant and productivity is low and energy consumption high compared with other techniques.

Fig. 30 Cumulative plot of REP particle size distributions. Weight percent of sample finer than a given screen size versus screen size. Electrode: C-1018 steel, 63.5 mm ($2\frac{1}{2}$ in.) diameter

The process has only been commercially operated by one firm and is effectively a very "niche" one, with a few highly specialized industrial applications and total annual output not exceeding 1000 tons/year.

Atomization

John J. Dunkley, Atomising Systems Limited, Sheffield, England

Models of Centrifugal Atomization

Centrifugal atomization is more amenable to detailed analysis (see Ref 1, 40, 41, 42) than two fluid methods because the velocity of the particles at the edge of the disk/cup is fairly well defined, in contrast to the very poorly defined velocity term in two fluid atomization theory. As melt flow rate increases, the mechanism changes from the formation of drops to ligaments and then sheets. The analysis of centrifugal atomization developed by Champagne and Angers (Ref 40, 41, 42) allows for a quantitative prediction of mean particle diameter in the direct droplet formation mode. In its present form, the model gives no indication of the spread of droplet sizes.

By simple force balance between centrifugal force and surface tension forces, the following expression can be derived:

$$d = \sqrt{\frac{A \cdot \sigma}{\rho_m \omega^2 \cdot R}} \quad (\text{Eq 17})$$

where ω is the angular velocity (rad/s) of the rotating disk (or the bar in REP) and R is the disk radius (m). A is a constant with value 6 in the elementary case.

From particle size distributions reported on the atomization of the Merl 76 (Ref 43), comparison is made between actual results and predicted results (Fig. 31). Mean particle sizes with the model are plotted as curve 1 in Fig. 31 for $A = 5.25$. Actual powder sizes are coarser than those predicted, which may be explained by the influence of viscosity particularly at higher speeds. In effect, the molten film is "slipping" on the disk surface, making its speed less than the peripheral speed of the disk. If a term that is counteracting the centrifugal acceleration and that includes both the viscosity and the speed at the rim of the disk is added to the basic model, the following relationship is suggested by Tornberg (Ref 24):

$$d = \sqrt{\frac{A \cdot \sigma}{\rho_m \cdot \omega^2 \cdot R (1 - (\omega \cdot R)^n \cdot \eta)}} \quad (\text{Eq 18})$$

In this curve, the constant $A = 4.8$ and the exponent $n = 0.93$.

Fig. 31 Calculated and actual powder particle sizes of Merl 76 superalloy powder made by centrifugal atomization (with disk radius of 45 mm). Curve 1 is a plot of Eq 17, which does not account for viscosity effect. Curve 2 is a plot of Eq 18 with a viscosity factor. Source: Ref 30

The reason why no significant effect of viscosity has been observed in REP atomization (Ref 42) can be explained by the relatively low speed at the rim of the small diameter rotating bar in REP and the very thin film due to the low melting rate of the process. The viscosity effect probably increases with increased disk velocity and thereby also metal velocity at the point where the metal leaves the disk to form a particle. The viscosity factor therefore includes both the radius and the angular speed of the disk. To reach high metal velocities in centrifugal atomization a large disk radius or a high speed of rotation is necessary. The mechanical limitations on radius and speed make it difficult to obtain the finest powder particles via centrifugal atomization. However, as Eq 17 shows, high density, low surface tension alloys are finer, and there are reports of powders as fine as 25 μm being made from dense alloys such as SnBi (Ref 1). This topic is discussed in Ref 44.

Champagne and Angers (Ref 41, 42) have demonstrated that a bimodal distribution of particle size occurs due to a mechanism in which liquid drops separating from the electrode rim remain connected momentarily by a necked-down column of liquid metal that breaks into smaller drops when the major spheroid is freed. This effect of bimodal particle size distribution is shown in Fig. 32. Although smaller particles are not present in large quantities by weight, their absolute numbers may be significant. It is this effect, giving rise to 3 to 8 μm particles, which can then form satellites by collision with larger particles, that has given some problems to electronic solder producers.

Other Methods

Ultrasonic (Vibrational) Atomization. This very specialized technique was, until recently, merely a laboratory curiosity, despite being reported as early as the 1960s. The principle is that a liquid film, if vibrated sufficiently strongly, will form waves that will in turn break off to form droplets. This effect is observable at low frequencies and has been demonstrated on metals such as zinc using low kHz frequencies in the Ukraine. However, it has recently been developed by several leading solder producers to make electronic solder powder for paste production. As mentioned above, this is needed with very narrow particle size and perfectly spherical shape.

The major drawback of the process is that, similar to the spinning-cup process, it places high demands on materials of construction for the solid surface. It must resist melt attack, be wettable (attack and wetting are two sides of the same coin, so this is always a compromise), and have suitable acoustic properties. Therefore, it is not surprising that it has not found application on higher-melting materials. However, it can be made to work on solders, although with a low output, typically 20 to 40 kg/hour (for one horn). Frequencies used range from 20 to 80 kHz, and the particle size distribution is practically free of ultrafine particles. Standard deviation σ_g of 1.4 or better is achievable, giving yields similar to centrifugal techniques and far better than gas atomization. Equipment is compact (typical vessel diameter less than 1 m) and energy use small (~ 1 kW). Production by this method is probably around 1000 tons/year (gross).

Other Methods of Atomization. Besides the industrial types of atomization processes, there are also many atomization methods of potential scientific interest that have been reported in the literature. These methods include:

- *Roller atomization:* A mechanical process that feeds a stream of molten metal between rapidly rotating rolls and discharging it into flake, acicular, or irregular spherical particles. This has been found to be generally impractical due to accretions on the rolls and very variable heat transfer to them.
- *Vibrating electrode:* This mechanical approach produces high-purity powder by the vibration of a consumable electrode. The electrode, forming a resonant rod with a fixed and free end, is continuously moved between rollers toward a slowly rotating, water-cooled copper disk. Atomization occurs in an arc struck between the disk and vibrating electrode end. The size of spherical particles formed is controlled by changing the length of the resonant rod. Productivity is low, cost high, and particles coarse.
- *Melt drop (vibrating orifice) technique:* In this method, molten metal contained within a closed, pressurized crucible is subjected to vibratory oscillations. Forcing the metal through a nozzle at the bottom of the crucible and into a vacuum or inert gas chamber causes it to form a jet and undergo Rayleigh breakup into very uniform droplets. Values of σ_g of less than 1.05 have been reported. The technique has been demonstrated with aluminum, beryllium, copper, lead, mild steel, and some superalloys (Ref 45) and has recently been proposed for solder (Ref 46). The technique is in limited industrial use in the 1990s, making precision solder balls for electronics with sizes in the range 500 to 1000 μm . It is limited as production is related to the square of particle size and nozzle blockage is obviously a worry for holes in the 200 to 20 μm range.
- *Variants of centrifugal atomization:* Besides the more common methods of the rotating electrode and rotating disk or cup processes, other methods include centrifugal impact atomization, shot casting, laser-spin atomization, and the Durarc process (Ref 1). Few of these are commercially exploited, but new variants on old ideas are frequently reported.

Milling of Brittle and Ductile Materials

Revised by Carl C. Koch, Materials Science and Engineering, North Carolina State University

Introduction

MILLING OF MATERIALS, whether hard and brittle or soft and ductile, is of prime interest and of economic importance to the P/M industry. Mechanical comminution is the most widely used method of powder production for hard metals and oxide powders. Secondary milling of spongy cakes of oxide-reduced, atomized, or electrolytic powders is the most common milling process; hammer and rod mills are used for this type of milling. Depending on the degree to which the material is sintered, either primary particle size distribution is reestablished during milling or larger agglomerates are produced.

Mechanical comminution is restricted to relatively hard, brittle metals (electrolytic iron or bismuth, for example), some reactive metals such as beryllium and metal hydrides, ductile metals used for producing metal flakes, and chemically embrittled materials such as sensitized stainless steel.

Increasing interest in metal powder with particle sizes that are finer than the particle sizes of powders produced by atomization has reactivated interest in milling, particularly in solid-state alloying or high-energy milling. However, milling of metal powders has received minimal attention to date. Research conducted on ball milling of metals is primarily proprietary and empirical, and thus restricted to specialized P/M applications. Objectives of milling include:

- Particle size reduction (comminution or grinding)
- Particle size growth
- Shape change (flaking)

- Agglomeration
- Solid-state alloying (mechanical alloying)
- Solid-state blending (incomplete alloying)
- Modifying, changing, or altering properties of a material (density, flowability, or work hardening)
- Mixing or blending of two or more materials or mixed phases
- Nonequilibrium processing of metastable phases such as amorphous alloys, extended solid solutions, and nanocrystalline structures

The milling operation fractures, deforms (cold works), or cold welds the impacted particles. Milling also may produce polymorphic transformations (Ref 1), as is the case with lead oxide and stainless steel (Ref 2). The specific effect that milling has on a powder depends on the physical and chemical properties of the powder, the vacuum, gaseous, or liquid environment in which the operation is conducted, and milling conditions. Selection of the milling process is based on the desired result of the milling operation, the behavior of the powder under milling conditions (if known), the characteristics of the powder, and the physical and mechanical properties of the material.

During milling, four types of forces act on particulate material: impact, attrition, shear, and compression. Impact is the instantaneous striking of one object by another. Both objects may be moving or one may be stationary. Attrition is the production of wear debris or particles created by the rubbing action between two bodies. This type of milling force is preferred when the material is friable and exhibits minimal abrasiveness. Shear consists of cutting or cleaving of particles and usually is combined with other types of force. Shear contributes to fracturing by breaking particles into individual pieces with a minimum of fines. Compression is the slow application of compressive forces to a body (crushing or squeezing of particulate material). This type of milling action usually is associated with jaw crushers and the breaking of large agglomerates of hard, nonductile material.

Design and process improvement has been based primarily on empirical and semi-empirical data. Advancement has been made in understanding the nature of brittle fracture of single particles of relatively homogeneous materials, such as glass. Fundamental research on milling ductile metals is lacking, although much is known phenomenologically about the process. Comminution is not adequately understood as it applies to the detailed mechanism involved when particles are impacted by colliding mediums.

Fracture occurs in hard, brittle materials, with minimal particle deformation and agglomeration by welding. Particle deformation results from attempts to comminute or blend particulate materials. Deformation, cold welding, and fracturing occur in varying degrees with both hard and soft ductile materials. Although powders of <100 mesh (<150 μm) are most frequently milled, particles up to 6 mm (0.2 in.) and larger can be processed.

Milling of Brittle and Ductile Materials

Revised by Carl C. Koch, Materials Science and Engineering, North Carolina State University

Principles of Milling--Phenomenological Description

The impact process is shown in Fig. 1. This model represents the moment of collision, at which particles are trapped between two colliding balls within a space occupied by a dense cloud, dispersion, or mass of powder particles. This phenomenon is typical in dry and wet milling operations that use colliding milling mediums such as tumbler, vibratory, and attrition ball mills.

Fig. 1 Model of impact event at a time of maximum impacting force showing the formation of a microcompact

The number of particles within the incremental volume subjected to impact compression stress may range from a single particle to several million, depending on the average particle size and the radius of the ball or curved surfaces contacting the trapped incremental volume. The number of particles trapped between two balls on impact in a loose powder mass should increase as the ratio of the ball diameter (D) to the particle diameter (d) increases. Also, the probability of a particle being trapped and impacted between the two balls increases as powder fill (percentage of space between the balls filled with powder) is increased and apparent density of the agitated or fluidized powder increases.

At the high ratios of D/d encountered in milling of fine particles (<100 mesh, or $<150 \mu\text{m}$), the trapped volume consists of particles within the microvolume $BB'BB'$ (Fig. 1). Outside this incremental volume, the apparent density of the powder sharply decreases to the density of the agitated loose powder.

The process of trapping an incremental volume between two balls within a randomly agitated charge of balls and powder, assuming no rotation or transverse motion of the curved surfaces, is shown in Fig. 2. Between the stages shown in Fig.

2(a) and 2(c), a certain volume of agitated powder is trapped between two impacting balls. The amount of powder trapped and the size of the trapped volume depends on many factors, including particle size, apparent density of the particle cloud, the presence of a slurry and its concentration and viscosity, air or gas pressure within the mill, surface roughness of the balls, and velocity of the balls.

Fig. 2 Process of trapping an incremental volume of powder between two balls in a randomly agitated charge of balls and powder. (a) through (c) Trapping and compaction of particles. (d) Agglomeration. (e) Release of agglomerate by elastic energy

In a gaseous atmosphere prior to impact, the majority of particles is ejected as the balls approach each other, while the remaining fraction becomes trapped and compacted between the decelerating balls at the moment of collision (Fig. 2a, 2b,

2c). If impacting force is sufficient, the trapped incremental volume of powder is compacted to form an agglomerate particle or pellet (Fig. 2d), which is released (Fig. 2e) when elastic energy impels the balls apart. If bonding by welding or adhesion occurs between contacting surfaces of the particles and bonding forces are sufficient, the agglomerate does not break apart. Similarly, particles may bond to the surfaces of the balls, which may become coated with the powder, as shown in Fig. 3 and 4.

Fig. 3 Grinding balls coated with powder (a) Cement. (b) Marble. (c) Silica. (d) Silicon. (e) Corundum

Fig. 4 Spikes of magnesium formed on 12.7-mm ($\frac{1}{2}$ -in.) diam balls. After prolonged milling under nonreactive milling conditions in a vibratory ball mill

If the compressive impact forces exerted by the balls and particles are sufficient, particles fracture or compact within a critical zone of diameter X_c and thickness (t), within the boundaries of $B-B'$ and $B-B'$ (Fig. 1). The initial zone of compaction theoretically does not exceed $AA'AA'$. The incremental volume of compacted powder consequently consists of surviving original particles and fragments of fractured particles. Surviving particles include those particles protected by larger particles that underwent fracture and fine particles that absorbed and dissipated impact force without fracturing. Density of the trapped bed of particles varies from the maximum at the point of first contact between the two balls ($C-C'$ in Fig. 1) to the density of the freely agitated powder outside the two $A-A'$ boundaries.

As the balls decelerate during impactation because of the cushioning effect of the trapped powder, a radial displacement of powder particles away from the line of contact $O-O'$ (Fig. 1) occurs in the direction of least resistance to particle flow. The greater the curvature of the balls, the greater the radial wedge effect acting on the trapped particles and the higher the velocity of ejection. Radial displacement of powder is resisted by interparticle friction and friction between particles and the ball surface. Such displacement is dependent on the roughness of the particle and ball surfaces and the degree of adhesive binding or cold welding between agglomerate and ball surfaces.

Comminution is similar to impact compacting of a radially unrestrained micropowder compact. Compaction begins with a powder mass that is characterized by relatively large spaces between particles compared to the particle size. The finished product is a mass of powder with comparatively small pores. The first stage of compaction consists of rearrangement and restacking of particles. Particles slide past one another with a minimum of deformation and fracture, producing some fines--especially from brittle, irregularly shaped particles. During this stage, flowability is reduced, and void spaces are partially filled with fine particles.

Particle shape plays an important role during this stage. Spherical particles, having the greatest flowability and least friction, are almost totally ejected from between colliding balls; pancake or flake particles, having the least flowability

and greatest frictional resistance to flow, tend to be retained between ball surfaces. Particles with irregular surfaces also tend to mechanically bond together to form an agglomerate.

The second stage of compaction involves elastic and plastic deformation of particles. During this stage, cold welding may occur between metal particles. Elastic deformation plays a relatively minor role, whereas plastic deformation and cold welding have major effects, depending on the ductility of the materials and the milling environment. For hard, brittle ceramic and metallic materials, plastic deformation and welding have little effect on comminution. However, plastic deformation and cold welding drastically alter the mechanism of milling for ductile metals. Most metals work harden during the second stage of compaction, which increases deformation resistance.

Finally, the third stage of compaction, involving particle fracture, results in further deformation and/or fragmentation of the particles. Densification of brittle ceramic and metallic particulate materials in the microbed occurs when small pores are filled with fragmented particles. Metal powder and soft ceramic particles achieve higher densities when pores are filled by flow processes.

As shown in Fig. 1, the density of the powder bed reaches a maximum at the core of the zone of compaction, C-C'. The strength of the microcompact formed at this point depends on the strength of the bonds between particles, which in turn depends on factors such as conformance of the bonding surfaces, oxide films, surface cleanliness, temperature, and impact force.

The size of the microcompact depends on the above factors, as well as on particle shape, surface roughness of the balls and particles, and the size of the balls and particles. Thus, particle-to-particle bond strength ranges from very weak for ceramics to very strong for metals. For most ceramic materials, the microcompact disintegrates because of weak van der Waals bonds and because of the release of elastic strain in the particles when the balls rebound.

The microcompact ranges from very small for slightly ductile nonmetals, such as sodium chloride, to relatively large for highly ductile metal powders, depending on powder characteristics and the type of attractive forces associated with particle size. Particle size and surface area ranges associated with surface forces are:

Particle size or surface area	Surface force
50-10 μm	van der Waals and low level chemisorption forces
10-0.1 μm	Chemisorption forces predominate
200-500 m^2/g	Chemisorption and valency forces
500-1000 m^2/g	Valency forces

If chemical species that tend to chemisorb on the surface of the particles in a dry or gaseous environment can be eliminated or reduced, larger and stronger agglomerates tend to form. If the species in the environment promote adhesion between particle surfaces, agglomerates tend to be larger. In general, chemical reactions between fluid or wet environments and powder inhibit agglomerate formation and assist comminution, especially for metal powders. The less reactive the milling fluid, the greater the tendency for particles to agglomerate by welding. Moisture in the powder promotes packing of large masses of powder in ball mills. Drying the powder at 100 °C (212 °F) or above often alleviates or eliminates this problem, especially with fine aluminum alloy powders.

Brittle Fracture. The Griffith theory assumes that a brittle material has minute cracks dispersed within it and that fracture emanates from these cracks (Ref 3). The stress σ_c at which a crack propagates depends on the size of the crack. The general form of the fracture equation for modes of loading that lead to catastrophic failure is:

$$\sigma_c = A \left(\frac{\gamma E}{c(1 - \mu^2)} \right)^{1/2} \quad (\text{Eq 1})$$

where A is a numerical constant that depends on crack geometry and its location, mode of loading, and dimensions of the particle (for example, A is $\sqrt{2/\pi}$ for the slit crack in an infinite sheet); c is the size of the crack, E is the modulus of elasticity, μ is Poisson's ratio, and γ is the surface energy of the milled substance. Thus, measured strength depends on the size of the crack, elastic properties, and surface energy. For brittle materials, γ is between 10^3 and 10^4 erg/cm².

The stress σ for fracture of a particle may be represented by:

$$\sigma = \sqrt{\frac{2Er}{L}} \quad (\text{Eq 2})$$

where L is the length of the crack, and r is the radius of the crack tip. When stress at the crack tip equals the strength of the cohesion between atoms, all new surface energy is supplied by the stress itself from elastic strain energy and corresponds roughly to the Griffith model.

Three types of flaws (facial, volume, or edge) have been identified by Gilvarry (Ref 4), with respect to location on the surface or interior of single particles. The initial fracture surface in a single particle usually starts in a facial flaw on the surface of the original particle. However, insufficient surface flaws exist to explain the large number of fragments formed in brittle fracture. When an internal flaw is activated, two surfaces in apposition are created, each of which contains flaws intersected by the propagating fracture. New fracture surfaces are produced in turn by fractures propagating from these volume flaws. Similarly, edges formed by intersecting fracture surfaces contain flaws distributed linearly along the edge (edge flaws), which on activation generate new fractures.

According to Gilvarry, the three types of flaws are distributed independently of each other, as a consequence of the randomness of fracture surface orientation and the fracturing stress. Activated flaws are distributed randomly, independent of any stress-producing fracture. More specifically, the position of a flaw within a domain is independent of the position of all other flaws. The probability of a subdomain containing a given number of flaws is independent of the number contained in any other subdomain. Single fractures are initiated by an external stress system that is relieved with the propagation of the first facial flaws. After initial fracture, flaws are activated by stress waves that are generated by the application and withdrawal of the external stress. According to Gilvarry, flaws exhibit a Poisson-type distribution.

During a milling operation, the conditions for single fracture are satisfied only occasionally. The amount of time and energy required to produce fracture varies with the grinding process and environment. As particle size decreases, flaw concentration and size diminish to a point where edge flaws no longer remain in the particles activated by stress (Ref 4). At this point, fracture stops.

Ultrafine Grinding of Brittle and Hard Materials. The primary function of a mill is to sufficiently stress as many individual particles of the charge as possible, to induce fracture with a minimum expenditure of energy. During milling, a major portion of the energy input is expended on various internal processes that do not contribute to particle failure. As grinding proceeds into the ultrafine region, fracture mode varies, and conditions that were insignificant when particles were relatively large gradually become controlling factors.

Eventually, the milling process reaches an effectiveness limit where the physical and chemical effects associated with surfaces, edges, and corners multiply to inhibit comminution. Edge length per unit volume varies directly with the square of specific surface area, and the number of corners per unit volume varies as the cube of specific surface area. Thus, the probability that an individual particle will be stressed to failure becomes increasingly small.

If the particle deforms plastically, fracture is difficult to induce, and the probability that stress will occur is reduced further. As fragments decrease in size, the tendency to aggregate increases, and fracture resistance increases. Particle fineness approaches a limit as milling continues, and maximum energy is expended. According to Ref 5, the following major factors contribute to grind limit:

- Increasing resistance to fracture
- Increasing cohesion between particles, with decreasing particle size causing agglomeration
- Excessive clearance between impacting surfaces, which is minimized as ball diameter or radius of curvature decreases

- Coating of grinding medium by fine particles that cushion the microbed of particles from impact
- Surface roughness of grinding medium (highly polished, hard mediums that retain a minimum root mean square surface roughness during milling are most effective)
- Bridging of large particles to protect smaller particles in the microbed
- Increasing apparent viscosity as particle size decreases
- Decreasing internal friction of slurry as particle size decreases, thereby reducing production of finer particles by wear mechanism and probability of impacting particles

Generally, as batch comminution proceeds over an extended time, the mean applied stress needed for particle failure increases, while the magnitude of local stresses available to initiate fracture decreases.

Milling of Single Particles. Particles and powders are classified according to particle size, particle size distribution, particle shape, and surface texture. These powder characteristics determine flowability, apparent density, color, sinterability, compactibility, and the properties of sintered products (Fig. 5).

Fig. 5 Effect of vibratory milling time on apparent density and Hall flowability of cobalt-base and titanium-base powders

Particle characteristics determine the manner in which particles are deformed or fractured and their resistance to breakage. Thus, the fracture mechanics of single particles must be considered in the selection of milling equipment and milling conditions.

Figure 6 illustrates the crushing of single particles between impacting balls. This condition is encountered in the milling of relatively large particles or a fraction of a powder, as with large granules of a ceramic material, hard metals, or large atomized particles of a ductile metal powder. Under these conditions, many single-particle impact events occur. With ceramics and hard metals, large brittle particles are rapidly reduced to fine and ultrafine powders. The milling of a brittle single particle is shown in Fig. 6(a). During milling of ductile metals (Fig. 6b), individual particles do not fracture, but deform and thereby undergo shape change with little or no change in mass (Fig. 7). Large single particles of brittle materials shatter into fragments, while ductile single particles deform, first into a pancake shape and then into a flake shape.

Milling of Brittle and Ductile Materials

Revised by Carl C. Koch, Materials Science and Engineering, North Carolina State University

Milling Parameters and Powder Characteristics

Grinding elements in ball mills travel at different velocities. Consequently, collision force, direction, and kinetic energy between two or more elements vary greatly within the ball charge. Frictional wear or rubbing forces act on the particles, as well as collision energy. These forces are derived from the rotational motion of the balls and movement of particles within the mill and contact zones of colliding balls.

Surface roughness of the balls is a significant factor in milling--the rougher the surface, the greater the frictional energy expended, thus causing increased abrasive action. Frictional forces exert a wearing action between particles in contact with one another and reduce particle size by attrition, producing wear debris. Impact forces effectively reduce particle size in grinding applications involving coarser particle fractions or hard and/or brittle materials.

Impact forces are desirable for deformation processing of metal powders, such as the production of flake powders. Figure 8 shows the change in flake width of iron powder with milling time in a vibratory ball mill. Attrition grinding is most effective in fine grinding both hard and ductile materials and in mechanical alloying. In most ball mills, particles are

subjected to both impact and attrition forces. When forces are highly energetic, welding may occur between powder particles, between the powder and the balls, and between powder particles and the walls of the chamber.

Fig. 8 Relationship between flake size and milling time for electrolytic iron milled in a Megapact vibratory ball mill. Source: Ref 6

Force of impact is directly proportional to the mass of the milling medium. Consequently, processing rate and the forces acting on particles are a direct function of the effective diameter and mass of the milling bodies. Actual collision forces vary widely from theoretical values because of the complex motion of the medium and varying velocity, path lengths, and trajectories of individual milling bodies. Milling fluid viscosity also effects collision rate.

Generally, the size and density of the milling medium selected are determined by the deformation and fracture resistance for metals. For hard, brittle materials, fracture resistance is the only selection criterion. Large, dense grinding mediums are used to mill larger and stronger particulates, whereas smaller diameter mediums are used for finer grinding. For example, ceramic beads having a diameter of 1.6 mm (0.06 in.) and a density of 3.9 g/cm³ may be used for reducing coarse, thin metal flakes to very fine flakes. Milling elements of such a small size cannot be used effectively in conventional tumbler ball mills. For fine grinding of tough, hard materials, tungsten carbide mediums are recommended.

Often, a compromise must be made in the selection of ball size and material. Although tungsten carbide balls are economical for use in small-scale experimental mills or for milling expensive materials, costs may be prohibitive for some large-scale milling operations. Some mediums, such as stainless steel grinding balls, may not be readily available in large quantities in certain sizes; thus, optimum milling conditions may not be satisfied.

The surface area and particle size of nonmetallic materials change continuously. Total surface area of the medium increases as particle size decreases. With metals, however, two additional factors must be considered in addition to comminution. Metal particles may agglomerate by cold welding at impact, thus consuming surface area and causing a shape change because of ductility and the ability to cold weld.

Thus, depending on the dominant process during milling (fracturing, welding, or microforging), a particle may (a) become smaller in size through fracturing, (b) grow in size through agglomeration by welding, or (c) change from an equiaxed shape to a platelet or flake-like particle by microforging. For metals, changes in surface area and particle size measurements do not provide a meaningful criterion for comparing the effect of changes in process parameters, competing milling processes, and equipment.

A more useful criterion for assessing the milling process is one that reflects the spectrum of structural and physical changes occurring in the metal and that is sensitive to differences in processing parameters. Microhardness measurement of individual particles large enough to accommodate the smallest Knoop or diamond pyramid hardness indentation provides a suitable measure of the effect of milling on metal powders, because hardness is a measure of cold work and internal defects produced by milling. As shown in Fig. 9, hardness measurement is most meaningful up to milling times that produce maximum levels of cold works.

Fig. 9 Effect of milling time on microhardness of Nickel 123 powder

X-ray line broadening is sensitive to both the amount of cold work and the refinement in crystalline structure that occurs with continued kneading and working of the metal well after saturation cold work. Changes in the deformation rate of a metal powder produced by a given set of milling parameters are shown by the relationship of x-ray line broadening to milling time (Fig. 10).

Fig. 10 Relationship between x-ray line broadening and vibratory milling time for Nickel 123 powder. Numbers in parentheses refer to coordinates of atomic planes in face-centered cubic structure

Energy Relationship

When a metal is plastically deformed by cold working, most of the mechanical energy of the deformation process is converted into heat. However, a small amount (approximately 5%) is stored in the metal, thereby raising its internal energy. The energy associated with permanent lattice strain or cold work is minimal for hard, brittle particles, but can be large for ductile materials. The energy expended to overcome the friction between particles is translated to heat and performs no useful work in milling.

If the temperature of the powder rises above a certain point, the cold worked metal particles may undergo recovery and recrystallization. Heat is generated by particle deformation, and by elastic deformation of metal grinding balls and grinding chamber walls. Figure 11 illustrates typical temperature versus milling time curves for dry vibratory milled Fe-27Ni-16Cr alloy powder (Ref 7). Generally, the temperature rises during severe cold working, abruptly falls just before cold work attains saturation levels, and then slowly decreases after extended milling times. Water-jacketed milling chambers usually are required for large, high-energy vibratory and attrition mills that reach temperatures above 200 °C (390 °F).

Fig. 11 Heating curve for 280 cm³ (17 in.³) stainless steel milling chamber during vibration milling of Fe-27Ni-16Cr

Milling Processes

Changes in powder particle morphology (Fig. 12) that occur during milling of metal powders are produced by the following processes:

Process	Symbolic designation
Microforging	M
Fracture	F
Agglomeration	A
Welding (atomic bonding)	A_w
Mechanical interlocking	A_m
Autohesion (van der Waals forces)	A_a
Deagglomeration	D

Fig. 12 Scanning electron micrographs of Haynes Stellite 21 cobalt-base alloy powder. Milled in ethyl alcohol with aluminum nitrate grinding aid. (a) As-received powder. (b) After 1 h. (c) After 2 h. (d) After 4 h. (e) After 8 h. (f) After 16 h. (g) After 32 h. (h) After 64 h

Microforging. The initial and predominant process during milling is compression shape forming of ductile metal particles by impact from the milling medium, as shown in Fig. 6(b). Individual particles, or a cluster of particles, are impacted repeatedly by milling medium so that they deform (flatten) with little or no net change in individual mass.

Fracture. After a period of milling, individual particles deform to the extent that cracks initiate, propagate, and ultimately fracture the particles. Fissures, cracks, defects, and inclusions in particles facilitate fracturing. Particles formed from irregular or spongy particles contain fissures and cracks that facilitate compression, fatigue failure, and fragmentation, compared to the smooth, relatively nonporous spheroidal particles formed by atomization. Some friable metals (antimony, bismuth, silicon, manganese, and chromium, for example) and brittle intermetallic alloys (such as copper-aluminum, aluminum-magnesium, copper-tin, nickel-iron, nickel-zirconium, and phosphorus-copper) can be milled easily into powders.

Agglomeration of particles may occur by welding, mechanical interlocking of spongy or rough surfaces, or autohesion. Autohesion is the molecular interaction of particles among themselves, characterized by van der Waals forces. Deagglomeration is a process that breaks up agglomerates formed by autohesion without further disintegration of the individual powder particles.

Mechanism of Milling--Phenomenology

One type of milling mechanism consists of an initial microforging stage in which particles are deformed in the absence of agglomeration by welding and fracture. Eventually, particles become so severely deformed and embrittled by cold work that they enter a secondary stage, during which the particle fracture by a fatigue failure mechanism and/or by the fragmentation of fragile flakes. Fragments generated by this mechanism may continue to reduce in size in the absence of strong agglomerating forces by alternate microforging and fracture. When fracture dominates and the role of microforging

is negligible in the absence of welding agglomeration, flakes continue to become smaller until molecular interaction occurs.

As particles (particularly flakes) become finer, coupling forces tend to become greater, and agglomerates become stronger. Eventually, milling forces that deagglomerate the particles reach equilibrium with the coupling forces present, and an equilibrium agglomerate particle size results.

When cold welding between particles occurs, the initial process is microforging. This is followed by a secondary stage involving a closed loop process of fracture (F), microforging (M), and agglomeration by welding (A_w) as shown in Fig. 13.

Fig. 13 A closed loop process of fracture (F), microforging (M), and agglomeration by welding (A_w)

Constant kneading, fracturing, and rewelding produce a composite particle that consists of fragmented original and composite particles. At later stages in the milling process, composite particles are composed entirely of fragmented composite particles. The degree of refinement and blending of the composite structure is a function of milling time, as is shown in Fig. 14 and 15 for wet-milled iron and dry-milled nickel powder, respectively.

Fig. 14 Electrolytic iron showing transverse cross sections of particles. Milled in heptane. (a) As-received

Fig. 15 Nickel 123 showing transverse cross sections of particles. Dry milled. (a) As-received powder. (b) After 4 h. (c) After 8 h. (d) After 16 h. (e) After 32 h. (f) After 64 h

After a period of time, cold welding and fracturing attain a steady-state equilibrium. Average particle size obtained at this stage depends on the relative ease with which agglomerates can be formed by welding, fatigue, and fracture strength of composite particles, and resistance of particles to deformation. Particle size distribution is narrow, because particles larger than average are reduced in size at the same rate that fragments smaller than average grow through accretion of smaller particles and wear debris produced by attrition.

This process is shown in Fig. 8 and 16. When a large number of fine particles are produced by attrition, the degree of refinement is very high. If particles are spongy, rough, or covered with asperities, microforging may be accompanied by agglomeration through mechanical interlocking.

Fig. 16 Narrow particle size distribution caused by tendency of small particles to weld and large particles to fracture

Dispersion of Oxide Films, Hard Particles, and Wear Debris

The strengthening effect produced by ultrafine oxide particles through solid-state or mechanical alloying is an important factor affecting final equilibrium particle size and the time required to reach equilibrium particle size. Oxide particles, derived from oxide films originally present on the particle surface and/or from oxygen in the chamber environment, become entrapped between cold welded surfaces by kneading. This process is illustrated in Fig. 17 using a fluid medium. The strengthening effect of the dispersoid, cold working, and the composite structure greatly increase toughness, strength, and fracture resistance of individual particles. Under these conditions, particles assume a more equiaxed shape. More importantly, the degree of hardening may limit the amount of structural refinement if milling energy is insufficient.

(b) Intermediate milling: nickel flake formation continues; flakes weld; embedding of dispersoid particles in nickel continues. (c) Final milling: multilayered nickel flakes fold and/or break and reweld; all dispersoid kneaded into milled powder. Source: Ref 8

Because the mechanical alloying effect depends on achieving the ultimate degree of refinement, sufficient energy is required for milling. More information on mechanical alloying of oxide dispersion-strengthened superalloys is in the article "Production of Nickel-Base Powders" in this Volume.

Milling Environment

Surface-active agents and lubricants generally are used to nullify the forces of welding (or autohesion) and thereby inhibit agglomeration. Surface-active agents adsorbed on a particle surface interfere with welding and lower the surface tension of solid material. Because the energy required for milling is equal to the product of new surface area generated times the surface tension, a reduction in surface tension results in the use of shorter milling times and/or finer powders.

Corrosion reactions between the metal and grinding fluid or environment in reactive grinding also facilitate comminution. The greater the corrosion resistance of a metal, the less effective are corrosive agents. For example, aluminum nitrate, an effective grinding aid for nickel milled in ethyl alcohol, is significantly less effective for either type 316L stainless steel or Haynes Stellite 21.

Milling of iron powder in water, a highly reactive environment for this metal, produces an ultrafine mixture of iron oxide and metal particles. Heptane is one of the least reactive fluid milling environments for metals. However, addition of a grinding aid such as cetyl alcohol may reduce agglomeration by welding. The effectiveness of a given additive depends on its reactivity with the metal being comminuted; the more reactive the metal, the more effective the additive.

Metal powders milled in organic or inorganic fluids retain small amounts of the fluid dispersed throughout each particle (Ref 8). Thus, hydrocarbons containing hydrogen and carbon and carbohydrates containing hydrogen, carbon, and oxygen are likely to introduce carbon and/or oxygen into the particle. The hydrogen subsequently escapes as a gas or is absorbed into the metal lattice on heating or sintering. For example, Fig. 18 shows the amounts of oxygen, carbon, and nitrogen picked up during milling of electrolytic iron in heptane. Hydrated aluminum oxide surface films on aluminum alloy powders produce blisters during subsequent rolling into sheet after solid-state blending, unless removed by heating at 370 to 480 °C (700 to 900 °F) in an inert atmosphere or in a flowing inert gas stream.

Fig. 18 Pickup of oxygen, carbon, and nitrogen in electrolytic iron. Milled in heptane in a Megapact vibratory mill. Source: Ref 7

Some metals, such as aluminum, nickel, and copper, react with certain alcohols during milling to form complex metallo-organic compounds. For example, aluminum reacts with isopropyl alcohol. Other metals, such as titanium and zirconium, may react explosively with chlorinated fluids such as carbon tetrachloride. Chlorinated fluids should never be used with reactive metals.

According to Arias (Ref 9), two classifications of chemical activity exist between metal powders and the milling environment--reactive and nonreactive milling. In reactive milling, metal powders react extensively with the milling fluid during milling. The metal powder is comminuted to a particle size much smaller than the starting powder. Balls, mill chamber walls, and powder of the same metal do not weld together during milling.

During nonreactive milling, the metal powder either reacts mildly or not at all with the milling fluid during milling. Powder particles weld together to a great extent during ball milling. Additionally, balls, mill chamber walls, and powder of the same metal may weld together during milling. Welding of powders to balls and chamber walls may occur even if they are made of different alloys.

Reactive and nonreactive milling may occur in wet or dry environments. Mechanical alloying consists of dry milling in a vacuum or an inert gas, or in a flowing gas that may be reactive. In mechanical alloying, the welding process may be controlled by monitoring the oxygen concentration in the grinding chamber (Ref 10).

Milling of metal powders produces external shape and textural changes and internal structural changes. The extent of these changes is determined largely by milling parameters, milling environment, and physical and chemical properties of the metal or alloy being milled. These changes in turn affect the physical properties of the metal being processed and the resulting consolidation products. Powder characteristics associated with milling include:

External

- Shape
- Texture
- Reflectivity
- Particle size and particle size distribution

Internal

- Composite structure or composite agglomerates
- Cold work (stored energy)
- High dislocation density
- Improved homogeneity (alloys)
- Finer structure (laminar structure)
- Refined crystallite size, nanocrystalline grain size
- Chemical composition (incorporation of gases and fluids from the milling environment)

Physical

- Mechanical properties (resistance to deformation and hardness)
- Physical properties (resistivity)
- Chemical properties (corrosion)
- P/M properties (apparent density, flowability, sinterability, compressibility, and sintered density)

Knowledge of the variables that influence characteristics of a milled product can be used to improve product performance and material properties and to achieve innovative P/M applications not possible by conventional metallurgy. Some of these include silicon carbide whisker-reinforced composites, oxide-dispersion-strengthened alloys, and superconducting compounds such as Nb_3Sn .

Milling Equipment

During comminution, the milling machine stresses the maximum number of individual particles in a powder mass to initiate fracture with a minimum of energy. The motion of milling medium and charge varies between types of mills, with respect to movement and trajectories of individual balls, movement of the mass of balls, and the degree of energy applied to impact, shear, attrition, and compression forces acting on powder particles.

Tumbler Ball Mills

In the tumbler mill shown in Fig. 19, the motion of the balls or rods depends on the rotation speed of the chamber walls. Balls may roll, or "cascade," down the surface of the charge in a series of parallel layers or they may project, or "cataract," into space, falling on the balls and particles at the toe of the charge below. A detailed mathematical discussion of the trajectories followed by balls and particles is given in Ref 11.

Fig. 19 Tumbler mill used for milling metal powders

Ball Mill Charge Parameters. The rate of milling of a powder is a function of the quantity of powder in the total volume between the balls and attains a maximum value when the powder fill is 100% (that is, the space between the balls is completely filled with powder) (Ref 11). Speed of the mill should be adjustable to ensure operation with the required proportions of balls for cataracting and cascading. This proportion is largely dependent on the speed of rotation and the coefficient of friction of the charge material. With increasing ball size, the rate of milling increases, attaining a maximum when balls reach sizes capable of crushing all particles in the feed powder.

If the slip of the charge against the mill chamber wall is assumed to be negligible, critical rotational speed of the mill may be calculated:

$$N_c = 76.6 \sqrt{\frac{1}{D}}$$

where D is the mill diameter, in feet; and N_c is the critical speed of the mill, in revolutions per minute. These parameters are approximate and may not be valid for metal particles that tend to agglomerate by welding.

Solid-state blending can be achieved in tumbler ball mills using 6 to 25 mm (0.25 to 1 in.) diam balls, if mill diameter is approximately 1.5 to 1.8 m (5 to 6 ft) and other conditions that promote cold welding agglomeration are satisfied. For large-scale production of mechanically alloyed superalloys, tumbler mills are replacing attrition mills. Milling times in tumbler mills are longer to accomplish the same level of blending achieved in the attrition or vibratory mill, but overall productivity is substantially greater. Tumbler mills usually are used to comminute or flake metals, using a grinding aid or lubricant to prevent cold welding agglomeration and to minimize oxidation (Ref 12 and 13).

Vibratory Ball Mills

Vibratory Tube Mill. In the laboratory vibratory tube mill shown in Fig. 20, oscillatory motion of the balls is complicated. The path of the balls and particles is determined by many factors, including vibrational speed, amplitude, curvature of the sides of the mill chamber wall, horizontal motion of the mill, and charge contact with the upper surface of the mill chamber. The balls gyrate around the chamber wall, sometimes traveling horizontally in a spiral path. Gyration in cylindrical chambers occasionally produces deformation and/or wear grooves in the inner walls of the chamber. These grooves may extend 360° or less, depending on whether the balls make contact with the upper surface of the chamber wall. Balls also revolve at different rates and directions, causing substantial shearing action, which is desirable in mixing and blending operations.

Fig. 20 Megapact vibratory ball mill. Courtesy of Battelle Memorial Institute

Impact forces acting on powders in a vibratory mill are a function of the rate of milling, amplitude of vibration, and mass of the milling medium. High-energy milling forces can be obtained by using high vibrational frequencies and small amplitudes of vibration. The mill shown in Fig. 20 operates at 3300 rpm, with a 2 mm (0.08 in.) amplitude, reaching a maximum acceleration rate of 12.2 g , where g is the gravitational acceleration at 9.81 m/s^2 (32.3 ft/s^2). Large production mills operate at relatively low vibrational frequencies and high amplitude (for example, 1000 to 1500 rpm and up to 12 mm, or 0.48 in.).

The vibratory ball mill is an excellent means of producing solid-state alloyed and dispersion-strengthened metals in amounts up to 4.5 kg (10 lb) or more, depending on the apparent density of the powder. Figure 21(a) and 21(b) show the microstructure of an aluminum-iron-cerium alloy and a transmission electron micrograph of oxide dispersion in the same alloy after solid-state alloying in a laboratory vibratory mill of the type shown in Fig. 20.

Fig. 21 Homogenization of Al-Fe-Ce alloy by high-energy milling. (a) Untreated rapidly solidified powder after hot pressing. (b) Hot pressed rapidly solidified powder after high-energy milling in a Megapact mill

In large tube mills of the type shown in Fig. 22, vibratory motion of the medium decreases from the chamber walls to the center of the mill tube; consequently, the milling effect is less at the center of the mill than adjacent to the chamber walls. Efficient operation is obtained at a ball fill of 60 to 80% of the volume of the mill chamber for tubes about 500 mm (20 in.) in diameter, with 100% fill of the volume between the balls.

Fig. 22 Pilot- and production-size vibratory mills

In vibratory mills, the grinding medium receives rapid impulses at a rate proportional to the vibrational frequency of the mill. Impact forces acting on the powder exceed shearing and friction forces. The entire charge slowly revolves counter-clockwise to the oscillatory vibrations, so that grinding and intense mixing occur simultaneously. Vibratory mills utilize smaller mediums because of higher impact forces, frequencies, and acceleration; thus, a higher specific surface is available for milling. The rate of processing in a vibratory mill is the following:

- Proportional to the density of balls (diameter constant)
- Proportional to the diameter of the balls (density constant)
- Proportional to the cube of the frequency of vibration
- Negligible for speeds less than 900 to 1000 rpm
- Proportional to the square root of ball diameter/mean particle diameter ratio

- Not significantly affected by chamber diameter
- Increased as amount of powder in mill decreases
- Greater with balls than cylinders or other shapes

Sweco vibratory mills (Fig. 23) are equipped with a grinding chamber in the form of a vertical cylinder with a solid center axis. A double-ended motor with eccentric weights rigidly attached to the bottom of the chamber generates high-frequency, three-dimensional vibrations. The chamber and motor assembly are mounted on a base and are supported by compression springs. Vibration of the grinding medium within the chamber creates the milling action. Vibrations are transmitted from the sides and base of the chamber to the grinding medium. Particles trapped within the medium are broken down by high-frequency impaction.

Fig. 23 Sweco vibratory wet grinding mill

The medium is packed to provide near-maximum packing density. The packed mass slowly gyrates horizontally, rises near the outer wall of the chamber, and descends as it approaches the inner wall. This motion facilitates distribution of the charge in dry grinding and serves to maintain solids in suspension in wet milling. The Sweco mill is not widely used to mill metal powders. It is particularly ill suited for high-density metals, because high density causes particles to settle to the bottom and become caked.

Attrition Mills

Milling in an attrition mill (Fig. 24) is effected by the stirring action of an agitator that has a vertical rotating shaft with horizontal arms. This motion causes a differential movement between the balls and the material being milled, thus providing a substantially higher degree of surface contact than is achieved in tumbler or vibratory mills.

Fig. 24 Attrition ball mill

Milling is accomplished by impact and shear forces. The rotating charge of balls and milling product form a vortex at the upper end of the stirring shaft, into which the milling product and balls are drawn. The milling product is impacted by balls traveling in various trajectories that collide within the dilated charge of medium and powder.

While ball mills use large mediums, normally 12.7 mm (0.5 in.) or larger, and run at low rotational speeds of 10 to 50 rpm, the attrition mill agitator rotates at speeds ranging from 60 rpm for production units to 300 rpm for laboratory units and uses mediums that range from 3 to 6 mm (0.125 to 0.25 in.). Power input to attrition mills is used to agitate the medium, not to rotate or vibrate the heavy containment vessel.

For hard materials such as ceramics, carbides, and hard metals, attrition mills are more efficient than conventional tumbler and vibratory ball mills. The main advantages of attrition mills for mixing and blending tungsten carbide/cobalt cutting tool powders include short milling time, production of fine particle size (submicron sized), and enhanced smearing of cobalt onto carbide particles. Attrition mills effectively mill metals in inert atmospheres, such as in solid-state or mechanical alloying processes, but are not cost effective. Product output is relatively low with attrition mills, compared to large tumbler and vibratory ball mills. Consequently, tumbler ball mills usually are used for production runs of over 135 to 180 kg (300 to 400 lb) per day.

Mechanism of Attrition Mills. The central rotating shaft of an attrition mill, equipped with several horizontal arms, exerts sufficient stirring action to tumble the grinding medium randomly through the entire chamber volume, causing irregular movement by the following:

- Impact action on the medium
- Rotational force on the medium
- Tumbling force as medium fills the void left by the shaft

For fine grinding, both impact and shearing forces must be present. In attrition mills, impaction is caused by constant impinging of the grinding medium, due to irregular movement. Shearing action is produced by random movement of the balls in different rotational directions, which exerts shearing forces on the adjacent slurry. The strongest medium agitation occurs at a point located two-thirds of the way from the center. Grinding does not occur against the chamber walls, which serve as a container rather than a grinding surface. Minimal wear of chamber walls ensures long service life.

In attrition grinding, grinding time is related to medium diameter and agitator speeds, within given limits, as:

$$t = \frac{kd}{\sqrt{n}}$$

where t is grinding time required to reach a certain median particle size; k is a constant that varies with the slurry being processed and the type of medium and mill being used; d is diameter of the medium; and n is shaft movement, in revolutions per minute.

Attrition mills are classified as batch-, continuous-, or circulation-type mills. In the batch mill, material is fed into the jacketed chamber and is ground until the desired dispersion and particle size are achieved. Premixing is accomplished in the grinding chamber. Chamber walls are jacketed so that either hot or cold water can be circulated to control and maintain the temperature of the batch. Batch attrition mills can process high-density material, such as tungsten carbide, as well as viscous materials, and are suitable for dry grinding and for processing dispersion-strengthened metals.

Continuous attrition mills, best suited for large production output, consist of a tall, narrow, jacketed chamber through which a well-remixed slurry is pumped in at the bottom and discharged at the top. Grids located at the bottom and top retain the grinding medium.

The circulation grinding system is comprised of an attrition mill and a large holding tank, generally ten times the volume of the grinding unit. The circulation attrition mill is filled with medium and contains grids that restrain the medium while the slurry passes through. Attrition mills generally have high pumping rates. Usually, the contents of the holding tank are passed through the system at a rate of ten times per hour.

One advantage of the circulation attrition mill is that large quantities of material can be handled with a minimum investment in grinding medium and equipment. The slurry can be monitored continuously, and processing can be stopped when the desired particle size dispersion is achieved.

Coldstream Impact Process

The Coldstream process is a high-velocity process in which material is entrained in a gas stream and projected against a stationary target. After material has struck the target and shattered, it is removed from the impact chamber by suction. Material is then transported to a classifier, which allows oversized products to drop into a storage vessel for subsequent impact against the target. The finished product is separated by the classifier and transported to collection containers.

The process chamber is lined with tungsten carbide or other wear-resistant material. The supersonic nozzle and target generally are made of cemented tungsten carbide, but other wear-resistant materials or the product being comminuted can be used to make these components. Figure 25 shows a high-speed closeup of a raw material stream impacting a target and shattering.

Fig. 25 Raw material steam impacting a target and shattering in Coldstream impact process

Rapidly expanding gases exiting the nozzle create a strong cooling effect through adiabatic expansion. This effect is greater than the heat generated by pulverization. Therefore, the process operates at well below room temperature. A compressor capable of operation at $56 \text{ m}^3/\text{min}$ ($2000 \text{ ft}^3/\text{min}$) at 6.9 MPa (1000 psi) is used. Such a compressor can operate two or three Coldstream impact systems simultaneously.

The Coldstream impact process is used to pulverize hard, abrasive, relatively expensive materials such as tungsten carbide, tungsten alloys, molybdenum, tool steels, beryllium, and other alloys. The process rapidly converts a feedstock of particles 6 mesh or smaller to micron size. Process benefits include simplicity, low operating cost, low operating temperature (which prevents oxidation), and the ability to retain high purity and particle size control over the material being pulverized.

Many standard products are supplied as atomized powders. The higher cost of additional Coldstream processing is justified by production of a finer powder than is commercially available by straight atomization. Most atomized powders have a slight oxide film on the surface of each particle, which is particularly noticeable in coarse powders of nonstainless steel composition. This brittle oxide film is stripped from the metal and broken up into fine dust during Coldstream processing. Lower density and smaller particle size facilitate separation from the metal particles by air classification. Coldstream processing generally produces a relatively oxide-free powder.

High-Energy Milling

Vibratory, attrition, and large-diameter tumbler mills may be classified as high-energy ball mills and, as such, may be used effectively in solid-state or mechanical alloying processes. Figure 26 provides the capabilities of typical size reduction equipment for grinding a material of a given feed size to a desired product size, when the milling objective is comminution of a hard and/or brittle metal or ceramic material. The following applications are suited to high-energy milling:

- Flaking metal powders (Ref 12, 13, 14)
- Mechanical alloying (Ref 6, 7, 10, 15, 16)
- Dispersion strengthening (Ref 5, 8, 16, 17)
- Composite powders (Ref 18)
- Particle shape control
- Control of powder flowability
- Apparent density control
- Tungsten carbide and tungsten carbide/cobalt alloys
- P/M alloy blending (Ref 18)
- Alloying of immiscible alloying elements (Ref 10)
- Particle size control
- Ultrafine powders (Ref 5, 19)
- Activated sintering (Ref 7)

Fig. 26 Typical size capabilities of common classes of size reduction equipment

With the explosion of interest in the last 15 years to use mechanical milling/alloying for production of metastable materials such as amorphous alloys, extended solid solutions, quasi-crystalline materials, metastable crystalline phases, and nanostructured materials, many laboratory-scale mills have been used for research. These mills typically use small quantities of powder, and in some cases, they are more energetic than the larger industrial mills. An often used mill used in research, especially in the United States, is Model 8000 shaker mill of Spex (Metuchen, N.J.). This high energy ball mill agitates the charge of powder and balls in three mutually perpendicular directions at approximately 1200 rpm. Ball velocities in such shaker mills are high, ~ 5 m/s. A given reaction, such as amorphization, can typically take place an order-of-magnitude faster in the Spex mill than in the usual vibratory or attritor mill.

Planetary ball mills also have been used often for research studies, particularly by European investigators. The vial containing the grinding media rotates about two separate parallel axes. A planetary arm of radius, R_p , is centered at a point about which it rotates at angular velocity, ω_p . The vial with radius R_v rotates (usually in the direction opposite to the planet arm) with angular velocity, ω_v . Typically, the commercially available Fritsch Pulverisette 5 (Germany) has been used. This mill also has been modified by some researchers for better control over the energy variation and milling temperature. There are several examples of specially designed mills for experimental research. These include the vibratory mill designed by Bakker and coworkers (Ref 20), which employs a single large steel ball (6 cm diameter) in a tungsten carbide lined steel vial which is attached to a vibrating frame. Calka and coworkers (Ref 21) designed an experimental ball mill, which can alter the milling action from predominantly impact to mainly shearing by changing the placement of strong permanent magnets, which are external to the vial. The recently developed Zoz horizontal attritor mill is produced for both laboratory and pilot plant powder quantities (Ref 22).

Ball Milling as a Nonequilibrium Processing Tool. The application of high energy ball milling that has stimulated the most research interest in recent years is its use as a nonequilibrium processing tool. It has been realized that mechanical alloying/milling can be used to synthesize metastable structures, in analogy to other nonequilibrium processing methods such as rapid solidification and physical vapor deposition. However, the precursor phase in the case of mechanical alloying/milling is typically a crystalline solid or solids rather than liquid or vapor. The thermodynamics and kinetic factors that govern metastable phase formation, therefore, can be very different. The variety of metastable structures that can be produced by ball milling are described in more detail in the article "Mechanical Alloying" in this Volume.

Modeling of the Milling Process. The qualitative descriptions of the physics/mechanics of the ball milling process discussed earlier in this article have been complemented by a number of attempts to quantify, that is, model, the process during the last ten years. McDermott (Ref 23) and Davis et al. (Ref 24) examined the mechanics of the Spex shaker mill. The model consists of a simplified version of the movements of the vial combined with the inferred ball movements based on classical mechanics and analytic geometry. The vial motion was recorded on videotape after slowing its apparent velocity by use of a high precision stroboscope. After digitizing these data, that is, ball displacements and velocities, a computer program performed calculations of a number of impacts for various ball and kinetic energy values. Martin and Gaffet (Ref 25) and Magini and Isonna (Ref 26) modeled the mechanics of ball milling in a planetary mill. A schematic of a planetary mill is given in Fig. 27. The Ω is the angular velocity of the ball mill plate, and ω is the angular velocity of the vials. The energy transferred per unit area scales with Ω^2 , and the frequency of the occurrence of the impacts scales with ω . It has been shown that plots of Ω versus ω provide maps of regions where certain metastable structures can be formed as illustrated in Fig. 28. Courtney (Ref 27) performed a number of modeling studies of ball milling. These results, as well as the results of others, are summarized by Courtney (Ref 27). The modeling is divided into two broad categories, local and global. Local modeling considers the mechanical action that transpires when powder particles are trapped between the colliding milling balls. Global modeling considers the characteristics of specific milling devices and how these affect the local impact events in the ball-powder-ball collisions. Courtney summarizes the modeling efforts with the warning that modeling of such a complex process can never be exact. However, at least partial success is achieved if the models identify the important material and process variables that determine the alloying kinetics, powder size, morphology, and so on. Indeed, such success has been achieved with some of the models.

Fig. 27 Schematic drawing of a planetary ball mill. The Ω and ω are the angular velocities of the ball mill plate and of the vials, respectively.

Hammer and Rod Mills

Hammer and rod mills are used in the P/M industry to mill large quantities of sinter cakes, which are intermediate products in the production of metal powders by reduction of their oxides. If such powders are to be used in conventional P/M parts processing, it is essential that they possess good green strength and compressibility characteristics. For these reasons, the sinter cakes must be ground into powder, typically -80 mesh, while introducing minimal cold work and densification. Hammer and rod mills with built-in screens or other separation devices are best suited to achieve these properties. Figure 29 shows the blocky particle shape of a copper powder produced by hammer milling of a porous sinter cake.

Fig. 29 Particles (+8 mesh) of copper powder hammer milled from oxide-reduced sinter cake. Courtesy of SCM Metal Products

Chemical and Electrolytic Methods of Powder Production

Reviewed and revised by Pierre W. Taubenblat, PROMET Associates

Introduction

CHEMICAL AND PHYSIOCHEMICAL METHODS of metal powder production allow great variations in powder properties. The wide variety of processing variables and production parameters currently available permit close control of particle size and shape. Powders made by reduction of oxides, precipitation from solution or from a gas, thermal decomposition, chemical embrittlement, hydride decomposition, and thermit reactions belong in this classification. The most widely used processes within this category include oxide reduction, precipitation from solution, and thermal decomposition.

Chemical and Electrolytic Methods of Powder Production

Reviewed and revised by Pierre W. Taubenblat, PROMET Associates

Oxide Reduction

The production of iron, copper, tungsten, and molybdenum powders from their respective oxides are well-established commercial processes. Detailed process descriptions for these oxide-reduced powders can be found in the articles "Production of Iron Powders," "Production of Copper Powders," and "Production of Refractory Metal Powders" in this Volume. On a smaller scale, oxide reduction is also used for production of cobalt and nickel powders.

Oxide-reduced powder grades of iron and copper compete with powder grades made by other processes. Oxide-reduced powders characteristically exhibit the presence of pores within each powder particle and thus are called sponge powders. This sponginess is controlled by the amount and size of the pores and accounts for the good compactibility (high green strength) and sinterability of such powders.

Processing conditions for oxide reduction, which are discussed in detail in Ref 1, are based on the generally known equilibria for the reduction reactions using hydrogen, carbon monoxide, and carbon as the reducing media, as shown in Fig. 1. The ratios of carbon monoxide to carbon dioxide, hydrogen to water, and the partial pressure of oxygen permit determination of the minimum ratios necessary to maintain reducing conditions at a given temperature and at a total gas pressure of 1 atm.

Fig. 1 Standard free energy of formation of metal oxides. To convert kcal to kJ, multiply kcal by 4.184. Source: Ref 1

In practice, however, reduction temperatures are usually much higher than indicated by thermodynamic data. Final powder properties such as particle size, particle porosity, and hydrogen loss that critically determine performance properties (apparent density, powder flow, and compacting and sintering properties) primarily depend on purity and size of the starting material and the kinetics of the reduction process. The kinetics of the reduction process depend on composition and flow rate of the reducing gas, reduction temperature, temperature profile in the furnace, and bed depth of the oxide if reduction is performed in a stationary system.

Improved reduction rates are possible with nonstationary reduction in rotary kilns or fluidized bed reactors because of improved access of the reducing gas to the metal oxide particles. For many reducible oxides, however, it is difficult to

control sintering and "freezing" of the fluidized bed. The former H-iron process (see the article "Production of Iron Powders" in this Volume), a fluidized bed reduction of iron oxide, used a high hydrogen pressure of approximately 3.5 MPa (500 psi) and a low reduction temperature of approximately 540 °C (1000 °F) to avoid freezing or caking of the bed. The low reduction temperature, however, caused the porous iron powder to be pyrophoric.

Process Variables. The various combinations of processing parameters used by powder manufacturers to produce numerous grades of powder are proprietary. The most important process variable is the reduction temperature. Typically, low reduction temperatures result in powders possessing fine pores, large specific surface areas, and high green strength. High reduction temperatures ($>0.6 T_m$) produce large intraparticle pores and small specific surface area powders that exhibit high compressibility. Extremely low reduction temperatures ($<0.3 T_m$) can readily produce pyrophoric powder. High temperatures can cause excessive sintering and agglomeration, which lead to difficulties with the breakup of the sinter cake.

With tungsten and molybdenum, oxide reduction is used partly for economic reasons, because the melting points of these metals are very high. Reduction processes, which use hydrogen as the reducing medium, are similar for both tungsten and molybdenum oxides. For molybdenum trioxide, however, reduction is performed in two stages to control particle size. Due to the high vapor pressure of molybdenum trioxide, the first step is carried out at 600 to 700 °C (1110 to 1290 °F). The second step, the reduction of molybdenum dioxide to molybdenum monoxide, is carried out at around 900 to 1100 °C (1650 to 2000 °F).

In contrast to atomized powders where oxides often are enriched on the surface of a particle, oxide-reduced powders, at least when freshly reduced or stabilized against tarnishing, contain most of their residual oxides within the particles.

Precipitation from Solution

Production of metal powders by hydrometallurgical processing is based on leaching an ore or ore concentrate, followed by precipitating the metal from the leach solution. Although basic precipitation reactions have been known for more than 100 years, commercial use of this process did not flourish until the 1950s, as a result of increasing interest and work on lower-grade ores. Metal precipitation from solution can be accomplished directly by electrolysis, cementation, or chemical reduction. Indirect precipitation can be achieved by first precipitating a compound of the metal (hydroxide, such as carbonate, or oxalate, for example), followed by heating, decomposition, and reduction.

The most widely used commercial processes based on hydrometallurgy are copper cementation and the separation and precipitation of copper, nickel, and cobalt from salt solutions by reduction with hydrogen (Sheritt Gordon process). In the 1960s and 1970s, several pilot plants using hydrometallurgical processing (solvent extraction and reduction with sulfur dioxide and hydrogen) were operating temporarily in the United States for the production of high-purity copper powder.

In its simplest form, copper cementation recovers copper from acidic dump leach solutions as an impure powder precipitate. Due to the presence of significant amounts of iron and silicates, low apparent density, and high green strength, such copper powders find use in P/M friction composite components. They are not used in conventional structural parts.

Nickel powders are now produced in large quantities directly from their ores by precipitation. The powder has a purity of at least 99.8%, with the major impurities being cobalt, iron, and sulfur, due to their presence in the original nickel ore. Powder can be produced in a variety of size distributions and is quite uniform. Similar techniques have been developed for cobalt.

Processing Conditions. For divalent ions, these processes consist of precipitation from an aqueous source using hydrogen. The basic concept is that a metallic ion such as nickel, copper, or cobalt in the solution reacts with gas (hydrogen) by the following reaction:

or if the solution is ammoniacal:

Generally, processing begins with leaching of ores and includes purification and separation stages prior to reduction. Reduction potential may be estimated by comparing the electrochemical potential of the metal ion and that of the hydrogen ions as a function of the partial pressure of hydrogen and pH of the solution. For reduction to occur, the hydrogen potential must be greater than the metal potential. Metal concentration has a minimal effect on electrochemical potential. These relationships are discussed in detail in Ref 2 and are shown in Fig. 2, which indicates that copper can be reduced in very acidic solutions. Higher pH values are required for nickel and cobalt. To obtain practical reaction rates, the actual process is carried out at elevated temperatures and pressures. For complete reduction, pH is increased by adding ammonia.

Fig. 2 Potential of 1 and 10^{-3} molar metal solutions and hydrogen potential at varying pH at 25 °C (75 °F). Source: Ref 2

Separation of metals is based on differences in the stability of complexed metal ions (ammines) subjected to hydrolyzing and oxidizing reactions. Potential-pH diagrams with the thermodynamics of oxygen reduction and hydrogen oxidation provide the necessary information to predict separation potential within a given system. Figure 3, a potential-pH diagram for the copper-ammonia-water system, is discussed in detail in Ref 3.

Fig. 3 Potential-pH diagram for the Cu-NH₃-H₂O system. Total NH₃ equals 1 mol/L. Source: Ref 3

The use of additives and control of nucleation, particle growth, and particle agglomeration allow the production of powders with a wide range of particle sizes, particle density, and particle shape with specific surface areas from less than 1 m²/g to about 8 m²/g.

Coprecipitation or successive precipitation of different metals from solution allows the production of alloyed and composite powders. Spray drying extends this capability to innumerable combinations. For more information, see the article "Spray Drying and Granulation" in this Volume.

Thermal Decomposition

Of the group of thermally decomposed powders, those produced by thermal decomposition of carbonyls are the most important. Both iron and nickel are produced by decomposition of the respective carbonyls.

Processing Conditions. Carbonyls are obtained by passing carbon monoxide over spongy metal at specific temperatures and pressures. Iron pentacarbonyl, Fe(CO)₅, is a liquid at room temperature, boiling at 103 °C (217 °F). Nickel tetracarbonyl, Ni(CO)₄, boils at 43 °C (109 °F). When the pressure is reduced to 1 atm and the temperature is

raised correspondingly, both of these carbonyls decompose to re-form the metal and carbon monoxide. The latter is recycled to form more carbonyl and to continue the process. These reactions are expressed as follows:

Powder is produced by boiling the carbonyls in heated vessels at atmospheric pressure under conditions that allow the vapors to decompose within the heated space and not on the sides of the container. The powder is collected and sieved and may be milled, followed by an anneal in hydrogen. The chemical purity of the powders can be very high (over 99.5%), with the principal impurities being carbon, nitrogen, and oxygen. Particle size can be controlled very closely. Iron carbonyl powder is usually spherical in shape and very fine (less than 10 μ m), while the nickel powder is usually quite irregular in shape, porous, and fine. Detailed descriptions of the iron and nickel carbonyl processes are given in the articles "Production of Nickel-Base Powders" and "Production of Iron Powders" in this Volume.

Electrodeposition

Electrodeposition of metals from aqueous solutions produces a variety of metal powders. This article discusses the methods used to produce powders electrolytically, and describes the types of metal powders made and their physical and chemical characteristics. Detailed information on the processing variables that permit close control of the chemical and

physical properties of electrolytic powders can be found in the articles "Production of Iron Powders," "Production of Copper Powders," and "Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum" in this Volume.

There are two practical methods of obtaining powder by electrodeposition: (1) direct deposition of a loosely adhering powdery or spongy deposit that can easily be disintegrated mechanically into fine particles, and (2) deposition of a dense, smooth, brittle layer of refined metal that can be ground into powder. For example, copper and silver produce powdery or spongy cathode deposits. Conversely, iron and manganese produce coherent cathode deposits; because these deposits will be crushed and ground into powder, it is highly desirable that they be brittle. Brittleness of the cathode deposit can be achieved by proper control of the electrolytic cell conditions.

Currently, only iron, copper, and silver powders are produced commercially to any extent by electrodeposition.

Direct Deposition

Direct deposition of powder or sponge on the cathode is achieved by controlling the composition (concentration of metal and pH), temperature, and rate of circulation of the electrolyte; current density; size and type of anode and cathode and their distance from each other; quantity and type of addition agent; and removal of deposits at the cathode (brush-down interval). These and other variables are discussed elsewhere in this Volume.

The shape of electrolytically produced powder particles depends on the metal deposited and the operating conditions. Electrolytic copper deposited from a sulfate/sulfuric acid electrode forms dendritic (fernlike) particles, as shown in Fig. 4. Silver electrolytic powder deposited from a silver nitrate solution generally is coarse and regularly shaped (Fig. 5). Electrolytic iron, copper, and silver are the most widely used powders made by this technique, but tin, chromium, beryllium, antimony, cadmium, lead, and zinc powders also have been produced by electrodeposition.

Fig. 4 Electrolytic copper powder, showing dendritic structure. 85×

Fig. 5 Electrolytic silver powder. 60×

Electrolytic copper powder has been produced commercially since the early 1900s. Modern practice, which utilizes a copper sulfate/sulfuric acid electrolyte, closely follows the original process developed in France.

Electrolytic copper production follows the same electrochemical principles that apply to copper refining. However, the conditions of electrodeposition are modified so that a powdery or spongy material is deposited on lead antimonial cathodes instead of the smooth, adherent deposit desired in electrefining. Formation of powder deposits is facilitated by

low copper ion concentration and high acid content in the electrolyte. High cathode current density and use of an electrolytically refined copper anode (instead of the impure cast copper anode used in refining operations) also contribute to powder formation.

Powder characteristics can be altered to a considerable extent by control of the operating conditions. Further size control can be achieved by use of addition agents such as colloids, which promote the formation of finer powders. The dendritic structure of copper particles is shown in Fig. 4. Details of the process variables and properties and applications of electrolytic copper powders are discussed in the article "Production of Copper Powders" in this Volume.

Electrolytic silver powder can be made by using a silver nitrate electrolyte and pure silver anodes. The powder particles deposited on the cathode are generally regularly shaped (see Fig. 5) and coarse, with particle sizes ranging from 40 μm to several millimeters, depending on the operating conditions and current densities. Details of the electrolytic and chemical processes are discussed in the article "Production of Precious Metal Powders" in this Volume.

Zinc Powder. The most recent metal powder to be produced electrolytically is zinc powder, which is made by using an electrolyte consisting of sodium hydroxide and sodium zincate. Zinc content is maintained at about 55 g/L to yield a deposit of suitable particle size. Current density is about 1076 A/m² (100 A/ft²). Under these conditions, the product is a loosely adherent sponge that can be easily scraped or brushed off the cathode and processed into powder.

Brittle Cathode Process

Metals characterized by high electrolytic polarization yield coherent deposits that can be made brittle under controlled operating conditions. Metals of this type include iron, manganese, nickel, and cobalt, with only iron and manganese being produced in commercial quantities.

Iron. Although electrolytic iron powders were made experimentally in the late 19th century, the first commercial production occurred in 1904. The electrolyte, composed of ferrous and ammonium sulfates, was maintained in a slightly alkaline condition. As a result, oxides were deposited along with the iron on the cathode, producing a brittle deposit that could be readily powdered. Steel anodes were used. The product was not particularly pure, but the application (electrical loading coils) did not require high purity. A later modification permitted the production of pure iron powder.

In modern practice, a chloride or sulfate electrolyte is used with soluble low-carbon steel or ingot iron anodes and stainless steel cathodes. Cathodes are stripped of deposited iron. The iron deposits are pulverized subsequently in ball or hammer mills, and the powder then is annealed in hydrogen to make it softer. The dendritic structure of the powder (see Fig. 6) is altered by crushing and ball milling to form irregularly shaped, flaky particles with a fairly rough surface. Details of this process can be found in the article "Production of Iron Powders" in this Volume.

Fig. 6 Scanning electron micrograph of electrodeposited iron sheet, indicating dendritic grain structure. 25×

Manganese powder is produced by electrodeposition from a purified manganese sulfate electrolyte using insoluble lead anodes and stainless steel cathodes. The brittle cathode deposit is readily removed. Because the powder is pyrophoric, it is ground into powder in ball or hammer mills under a protective atmosphere.

Ultrafine and Nanophase Powders

Introduction

ULTRAFINE POWDERS are typically defined by particle size distributions in the submicron range (Fig. 1) with equivalent diameters of approximately ten to a few hundred nanometers. Ultrafine powders are not new, but only until recently have engineers and applied scientists realized their potential in producing nanocrystalline (or nanophase) materials, in which the distance between neighboring defects, grain boundaries, or interphase boundaries is in the order of interatomic spacing.

Fig. 1 Size range and powder production methods

This article briefly reviews dedicated processes that have been developed to generate economical yields of fine and ultrafine metal powders. Fine metal powders have been commercially available for many years, and metal powders as fine as 3 μm are produced economically by atomization methods. Particle size distributions as low as 1 μm are possible with atomization, although precipitation and carbonyl vapor deposition processes are normally more economical methods near the ultrafine regime.

Ultrafine (submicron) powders can be produced either by physical or chemical methods. Neither mechanical grinding nor conventional (gas or liquid) atomization can produce powders extending into the submicron size ranges (the electrohydrodynamic atomization technique is a special case, of interest only for research production of milligram quantities). Mechanical alloying is of interest because it can produce powders, which in many cases have a nanocrystalline microstructure. However, it cannot produce ultrafine powders directly.

Ultrafine and Nanophase Powders

Fine Metal Powders

Ralph H. Hershberger, UltraFine Powder Technology Inc.

Fine metals have been commercially available for years by various methods. One of the earliest methods was the precipitation of elemental precious metal powders. Fine refractory metal powders are also produced by milling.

Elemental iron or nickel powders are also produced to fine particle distributions with the carbonyl process. On a tonnage basis, carbonyl iron still accounts for a large percentage of fine powders used for metal injection molding. Carbonyl iron is produced to very tight distributions (Table 1) with typical particle sizes ranging from 3 to 8 μm . Tables 2 and 3

summarize carbonyl iron grades from BASF, which is the world's largest supplier of carbonyl iron. More information on carbonyl iron is also contained in the article "Production of Iron Powder" in this Volume.

Table 1 Typical composition and particle size distribution of carbonyl iron powder

BASF grade	Mean size, μm	Iron, wt%	Carbon ^(a) , wt%	Nitrogen ^(a) , wt%	Oxygen ^(a) , wt%	Other	Particle size distribution

Some alloy parts are produced using elemental carbonyl iron and/or nickel as a base, but this method has obvious chemical limitations. In this regard, prealloyed powders from atomization offer more flexibility in alloy composition. So-called "residual products" met the initial demand for fine, prealloyed powders. Prior to 1980, the demands for fine alloy powders were satisfied by screening the fine residuals from a standard as-atomized distribution. Although this method avoided investment in technology development and dedicated equipment, it had several weaknesses. First, the supply of fine powders was constantly at risk. The available fine powders were a function of the production and sales of a coarse powder stream. This dependency jeopardized the supply continuity. Secondly, the powders frequently were not discrete particles and had satellites or were dog-boned shaped. Finally, if the products were sold on an as-yielded basis, the prices were prohibitively high and few markets could support production. Until manufacturers became convinced that a sustainable fine powder market existed, end users had to contend with these limitations. Ultimately, the limitations of residual fines prevented further growth.

Today a full range of fine alloy powders are produced by atomization methods (Table 4). Ametek, Specialty Metals Division in the United States, uses a specialized high-pressure, water-atomized system. Pacific Metals (PAMCO) of Japan uses high-pressure water and a recently announced combination water- and gas-atomization system (Ref 1). Mitsubishi employs a water-atomized process to create a feedstock, which is subsequently cold worked to create nodular shape powders. The primary commercial gas-atomization operations include UltraFine Powder Technology in the United States, Anval in Sweden, and Osprey Metals in Wales.

Table 4 Major commercial fine atomized powder producers, systems, and products

Country	Producer	Powder production system	Grades produced
Japan	Pacific Metals (PAMCO)	High-pressure water	Stainless, tool steels, nickel and cobalt alloys
	Mitsubishi	High-pressure water, shape modified	Stainless, tool steels, nickel and cobalt alloys
	Kobe	Water atomization	Stainless and tool steels
Sweden	Anval	Nitrogen gas atomization	Stainless steels
		Plasma-heated tundish	
United Kingdom	Osprey	Proprietary gas atomization	Stainless, tool steels, low alloy, and cobalt alloys
United States	UltraFine Powder Technology	Proprietary gas atomization	Stainless, tool steel, low alloy steels, copper, nickel, and cobalt alloys

Atomization Methods

All atomization processes convert the kinetic energy of the atomizing media, into surface free energy to form powder particles. The greater the energy introduced to the system, the greater the energy available for particle formation. Because smaller particles have a higher surface-to-volume ratio than larger particles, the mean size for the as-atomized particle distribution is reduced. For water atomization, this relationship was described by Grandzol (Ref 2) to be:

$$d_m = A/V_w$$

where d_m is mean particle diameter of the as-atomized distribution, V_w is water droplet velocity, and A is a constant.

Atomization is a notoriously inefficient energy conversion process. Conventional water atomizing systems are only $\sim 5\%$ efficient, and gas atomizing is even less efficient, converting $<1\%$ of the kinetic energy into surface free energy (Ref 3). Nonetheless, typical powder distributions for water-atomized products contain a significant amount of particles below $45\text{ }\mu\text{m}$ (see the article "Atomization" in this Volume).

In residual fines, particles below $45\text{ }\mu\text{m}$ must be separated. This step in fine powder production is commonly done by either screening or classification. As powders become finer, screening is less viable because the particles tend to blind the screen openings.

For particles in this size range, classification is the preferred method for size separation. Unfortunately, classification is inefficient, with recovery rates between 65 and 40% of the particle sizes present, depending on the cut point.

For fine powder to be produced, more energy must be introduced into the system per material atomized than is required for conventional atomization. The common measurement is a water/metal or gas/metal ratio. Three factors must be optimized: atomizing media mass, flow rate of the quenching media, and flow rate of the liquid metal. The energy available from kinetic energy is $(\frac{1}{2}mV^2)$, which is linearly proportional to the mass but to the square of the media velocity. This suggests higher flow rates of atomizing media, that is, water or gas, which requires higher pressure pumping systems to deliver the quenching media to the molten stream. Because pumping systems have natural limitations, to transfer sufficient energy, the water/metal or gas/metal ratio must include a reduction in the metal flow rate.

Typical flow rates for a conventional water-atomization system are 150 lb/min (Ref 4). For conventional gas atomization the rate is closer to 40 lb/min, and in some fine powder systems, the rate drops to 10 lb/min. This places an additional strain on the refractory system because the melt must be held at temperature for a longer period of time to complete the atomization run.

Another key factor in the process is the atomizing jet design. Manufacturers consider this element of the system to be a key factor in the viability of their process, and designs are seldom released publicly except as part of licensing packages. Lawley (Ref 4) has published an excellent review of atomization jet designs. Most fine-powder atomization systems employ some type of a close-coupled system to provide real-time feedback. During gas atomization, other factors physically limit the production. Because gas is significantly less dense than water, much higher flow rates must be used to deliver enough gas momentum and kinetic energy through the atomizing nozzle to the metal stream. This places extreme demands on pumps, hoses, couplings, and other plumbing. These technical difficulties are accompanied by economic issues associated with the scale up of these systems, which render many designs uneconomical for commercial use.

High-Pressure Water Atomization. Work performed by the National Research Institute in Japan has resulted in commercial water-atomizing systems, which have been adopted by Ametek and Pacific Metals. Typical properties for gas- and water-atomized products, as presented by the various processes, are shown in Table 5 (Ref 5). Figures 2 and 3 show the morphology of the same powders.

Table 5 Comparative properties of gas- and water-atomized powders

Properties	Gas atomized standard	Water atomized
Tap density, g/cm³	4.83	4.20
Pycnometer	7.685	7.649
Carbon, wt%	0.03	0.085
Oxygen, wt%	0.055	0.45
Distribution		
d₁₀₀	52.00 m	44.00 m
d₉₀	31.00 m	22.00 m
d₅₀	15.40 m	11.50 m
d₁₀	6.40 m	4.60 m

Gas Atomization. The first company to dedicate itself to fine powders was UltraFine Powder Technology. Their process (Fig. 4) employs two zone vacuum chambers, an atomizing chamber, and a gas recycle system. This allows for the upper and lower chambers to have independent pressures, which are key to the process.

Fig. 4 Schematic of the ultrafine powder gas-atomization system. Raw materials are melted in a vacuum induction furnace (1, 2), and a lower pressurized chamber (3) receives powder from the atomization die (4). Powder is removed from the lower chamber into cyclones (5) and collection bins (6). Pressurizing atomization gases are recycled (7, 8) and liquefied. At the beginning of a new atomization cycle, the gases are evaporated and reintroduced into the system (10).

Raw materials are melted in a conventional induction melt furnace inside an evacuated upper chamber. When the melt approaches the proper temperature, stopper rods are pulled from the bottom of the crucible, and the metal flows through the orifices and atomizing jets. Figure 5 shows a typical as-atomized distribution for copper and 17-4 PH stainless steel.

Fig. 5 As-atomized distribution for copper and 17-4 PH stainless

This system has the advantages of relatively large heats (up to 1270 kg); adaptability for argon, nitrogen, or helium atomizing gases; and an argon recovery/recycle system. It presently accommodates ferrous-, nickel-, cobalt-, and copper-base alloys. Figure 6 shows a typical 316L stainless particle.

Fig. 6 Scanning electron microscopy of 316L stainless steel gas-atomized powder

The Osprey Process. Although Osprey process atomizing devices were originally developed for the production of spray-deposited preforms, they also can be used to produce high-purity powders in a wide controlled range of particle size distributions (Ref 6 and 7). Powders produced using Osprey atomizers include silver and gold brazing alloy powders, tin-lead soldering powders, aluminum-magnesium powders for explosives, copper-tin-lead bearing alloys, and nickel- and cobalt-base hard-facing alloys. In addition high-melting-point alloys such as nickel superalloys (Fig. 7), Alnico permanent magnet alloys, and stainless steel powders have been produced using Osprey atomizing equipment.

Fig. 7 Osprey atomized superalloy powder (MAR M002)

Alloys that have been processed by the Osprey forming process include stainless steels, high-speed steels, and nickel-base superalloys, although many materials appear to be compatible with the process. Alloy development has centered on high-alloy ferrous metals, Stellite alloys, superalloys, and composite materials. Because an inert atmosphere is maintained during spraying, oxygen levels similar to conventional ingot metallurgy products are attained, typically in the range of 20 to 40 ppm for superalloys. The high preform density ensures that no interconnected porosity is present in the preform, preventing internal oxidation during transfer of the material to subsequent consolidation and forming operations. (See the article "Spray Forming" for more information on the production of preforms by Osprey.)

In terms of atomization, Osprey systems have equipment common to other gas-atomization systems, for example, pressure chamber, furnace and tundish, atomization nozzles, and collection chambers. The key difference between the Osprey system and other high-pressure gas systems is that it involves atomization by ultrasonic agitation. The process produces an as-atomized distribution (Table 6) that falls between the distributions of a carbonyl process and high-pressure water atomization. Osprey is commercial for heats up to 250 kg across a wide range of alloys.

Table 6 As-atomized diameters for various alloys produced by the Osprey system

Alloy	Mean particle diameter as-atomized, μm
D2	12.90
M2	15.8
Ti5	10.43
T42	12.57
FeSiB	14.21
Ni21Cr9Mo4Nb	10.49
FeCrNi	10.45
304L	13.9
316L	13.0
317L	13.85
17-4PH	13.59
310S	14.95
434	16.14

Source: Ref 8

Anval Gas Atomization System. The Anval system is a modified close-coupled, dual-nozzle atomizing system. Melting is performed in a five metric ton, air melt, tandem furnace system. Atomization occurs after the metal has been poured from a plasma-heated tundish (PHT), which removes many of the oxides normally found in air melted products. The system produces large batches of metallurgically clean, spherical powders typical of a nitrogen gas-atomized system.

Powder Comparisons. Atomization methods are capable of producing powder distributions as fine as 1 μm , but they are effectively limited to 3 μm for general production. Precipitation and carbonyl vapor deposition processes are normally more economical methods to create fine particles in the range.

The primary differences between water and gas-atomized fine powders are:

- Shape
- Purity level, that is, residual gas levels
- Production costs

Gases have a lower heat-carrying capacity than water so the metal stream does not quench as rapidly in a gas-atomized system. The residence time of a liquid droplet in the atomizing chamber is longer in a gas system than a water atomizer. This additional time permits the driving forces to minimize the surface free energy by forming a sphere. Although this effect is somewhat alloy dependent, fine gas-atomized powders are generally more spherical than water-atomized products. Because most of the commercial fine gas-atomized powder systems are vacuum or atmosphere controlled, the typical values for oxygen and nitrogen are lower than water-atomized powders. For applications that do not reduce the soluble gas levels in process, this is a critical difference. The third difference is production cost. On a momentum transfer basis, water is significantly less expensive than gas. Water systems do not require the special plumbing associated with gases and their subsequent recovery. In addition, the elimination of a vacuum cycle allows water-atomized systems to be configured to have a shorter cycle time than gas-atomized systems.

Typical vacuum-gas systems include a 1 to 2 h vacuum cycle, a 1 to 2 h melting time, and a 1 to 2 h atomization time. Cooling time for the atomized powder is additional. A typical 500 kg water-atomized heat can turn around in melt and atomize in 2 h. With dual tundishes, it can be run on a semi-continuous basis.

All of these reductions in equipment mean that the capital costs and resultant depreciation are lower for water-based systems compared with gas atomizers. An excellent treatment of these variables has been performed by Dunkley (Ref 9). The remaining factors of labor, yield, and overhead tend to be producer specific.

Ultrafine and Nanophase Powders

Applications

The physical and economic differences between the two types of powders result in clearly defined applications for each. Fine powders are used in both consolidated and unconsolidated forms. Markets include metal injection molding (MIM), electronic pastes and inks, thermal spray, additives, radar absorption coatings, and filtration.

Metal Injection Molding. The growth forecasts for MIM encouraged development of fine powder production processes. The first MIM parts were made from available powders generated by carbonyl (iron or nickel) processes. On a tonnage basis, carbonyl iron still accounts for a large percentage of the powders used by MIM. Nonetheless, both water- and gas-atomized powders are used extensively in MIM. Typically water-atomized powders are used to improve green strength and lower costs, while gas-atomized powders are preferred for moldability, lower oxide content, and tolerance control.

Electronics. Precious and nonprecious metals are used in the electronics industry for inks and pastes, conductive path, and capacitor terminations. Due to the extreme space limitations that these applications impose, finer distributions, ($<10\text{ }\mu\text{m}$) are required (Ref 10). Because atomization yields for all but a few elements in this range are extremely low, precipitation is a more economical production method, especially for precious metal formulations. Because copper has a low viscosity and atomizes easily, it is an exception, and it is available as either a precipitated or atomized product in these size ranges. The powders are blended with a polymer and applied to a substrate via precise silk screening techniques. Continued miniaturization is driving these applications into the submicron power range.

Thermal Spray. Thermal spray equipment has evolved to produce extremely dense metallic coatings. Gas-atomized powders have always been preferred over water-atomized powders for both fine and coarser distributions. The spray process favors spherical, free-flowing particles over irregular water-atomized particles.

Two types of equipment have been designed that require fine powders. Plasma equipment requires powders in the 5 to 45 μm range, and high velocity oxygen fuel (HVOF) equipment requires an even tighter range of 15 to 45 μm , with controlled intermediate ranges. Although HVOF has been enthusiastically embraced for carbide coatings (carbides had the most room for density improvement offered by HVOF), metals are a significant part of the HVOF supply mix. The market for fine powder from dedicated production processes is primarily an economic market. Metal alloys have always been available from fractions of coarse as-atomized distributions. The opportunity for dedicated fine powder systems is to supply these distributions in higher yields and lower overall costs.

Additives. Many industrial products are formulations of many particulate constituents. The most cost effective production method for these powders is normally grinding, but grinding has drawbacks. Grinding can lead to explosions, can introduce contaminants such as dirt and oxygen, and can generate a wider than desired particle size distribution. For these reasons, fine powders produced by the methods discussed in this chapter have found a niche in specialized applications where purity, size control, and distribution consistency are necessary.

Metal filled polymers require a consistent size distribution and shape to achieve desired properties. Conductive polymers need high-conductivity powders with low or controlled oxygen levels. In some cases, applications of fine powders are required to ensure an even loading in the polymer structure.

Grinding wheel formulations use fine-atomized powders because they disperse more uniformly than coarse distributions. The lower oxygen levels of gas-atomized products allows sintering at lower temperatures.

Radar Absorption. Although most of this work remains classified, fine carbonyl and prealloyed powders have been used in radar absorption coatings for stealth fighter planes. Soft magnetic compositions are used in fine sizes, which offer the best combination of absorption and weight reduction. Below the Curie point, carbonyl iron is cost effective. Above the Curie point, prealloyed materials are necessary to maintain performance. Table 3 lists two grades of microwave absorbing carbonyl powders.

Filtration. Metal filter media is used in very demanding and corrosive applications. New applications require removal of finer and finer particles. Clean room applications are the most demanding, and this places tremendous demands on filter-reduced pore size and control. Smaller particles can create finer pore sizes. Typical compositions are 316L and 304 stainless and Hastelloys. The preferred morphology is an irregular shape that provides green strength during the fabrication process, which favors water-atomized particles. However, in extremely corrosive environments, the purity of gas-atomized particles makes them a preferred material.

Magnetic Power Cores. Fine carbonyl iron powders with suitable insulator coatings improve the performance of electrical power cores. It is possible to achieve a substantial reduction in eddy current losses compared with cores produced from coarser powder. This reduction in eddy current losses is achieved when the insulation breaks conduction between the individual, primary powder particles.

Figure 8 shows circuit quality with two types of carbonyl iron powder as a function of the frequency and the degree of insulation. The insulation was carried out with a 60% phosphoric acid. The powders, insulated and bound with 5% Epikote, were compressed with a compaction pressure of 0.6 GPa to rod cores having a diameter of 9.2 mm and a length of 20 mm.

Fig. 8 Circuit quality with different levels of insulation on the primary carbonyl iron powders. See Table 3 for powder designations. Courtesy BASF

With an increasing degree of insulation, the quality at first increases, and then reaches a saturation value typical for the particular powder. The thickness of the insulating layer depends on the proportion of phosphoric acid. This depresses the content of the pure iron, and so the permeability falls (Fig. 9). This means that the gain in quality is detrimental to the permeability.

Fig. 9 Effect of powder insulation on permeability. Courtesy BASF

It is therefore necessary to find a compromise between sufficient additions of an insulating material for high quality without excessive reduction of permeability.

The aim of the insulation is to cover the powder particles with a layer that is as thin as possible, but completely surrounds the powder particle. The layer should also be thick enough to prevent damage during compaction under high pressure. Finally, the binding agent content also has an effect on quality and permeability. A higher binding agent content improves quality within certain limits, but also reduces the permeability.

Ultrafine and Nanophase Powders

Metallic Nanopowders

Harald Eifert, Fraunhofer Resource Center--Delaware Bernd Günther, Fraunhofer Institute IFAM

Today there are a number of established applications of ultrafine powders or nanocrystalline materials. At present, applications are essentially limited to magnetic recording media and nanocrystalline soft magnetic materials used in transformer cores (Ref 11, 12). However, the potential applications in advanced engineering and technology are numerous. Some of the applications already under development are:

- Electrically conductive inks or pastes
- Catalysts
- Sintering accelerators
- Microfilters
- Magnetic recording media
- Magnetic fluids
- High-strength/high-temperature construction materials
- Nanocomposites
- Drug carriers
- Radar absorbing coatings
- Wear-resistant coatings (tool materials)

Compared to ceramic processing, metal nanopowders are much more difficult to process and handle than powders in the micron size range. Nevertheless, different applications require metallic nanopowders and different production processes to serve this need. This Section provides an introduction in the different processes commercially used to produce metal nanopowders with specific emphasis on gas phase techniques for production of powders with a low-impurity level. Example applications describe the state-of-the-art methods in using metal nanopowders in industry.

The term nanopowder is usually used to describe powders with a particle diameter of $<1 \mu\text{m} = 1000 \text{ nm}$ (Fig. 1). Nanoscale powders have been used in the paint coating industry in tremendous volumes for decades--if made from carbon and metal oxides. Pigment soot, also named carbon black, is a carbon nanoscale powder with particle size 10 to 100 nm and is probably the most prominent example of this type of nanopowder. Nanoscaled silica powders are used as filler additives for a variety of organic suspensions in order to tailor their rheological behavior. The use of ultrafine carbide and nitride powders provides hardmetal tools with a remarkable increase in bending strength resulting in an extended time to failure.

The term nanopowder is also used to designate important changes in properties with the reduction of particle size. In this context the term is sometimes used for powders smaller than a certain threshold, where a dramatic change in properties occurs. Changes in properties can be caused, for example, by the increase in surface atoms of nanopowders. Figure 10 (Ref 13) shows the relative amount of surface atoms of powder particles as the function of the particle diameter.

Fig. 10 Percentage of atoms in grain boundaries of a nanophase material as a function of grain diameter, assuming that the average grain boundary thickness ranges from 0.5 to 1.0 nm, that is, ~ 2 to 4 atomic planes wide. Source: Ref 11

Nanoscale materials are used for production of advanced material components in three different types, as shown in Fig. 11. A nanocrystal or nanocrystalline material is a dense material with grain sizes in the nanometer range. Nanopowder is often used as aggregated powder particles, either as a suspension or as a loosely packed layer. A nanosuspension, or nanodispersion, is usually the name for a suspension of single nanoparticles, either in a liquid or in a solid matrix (Ref 14).

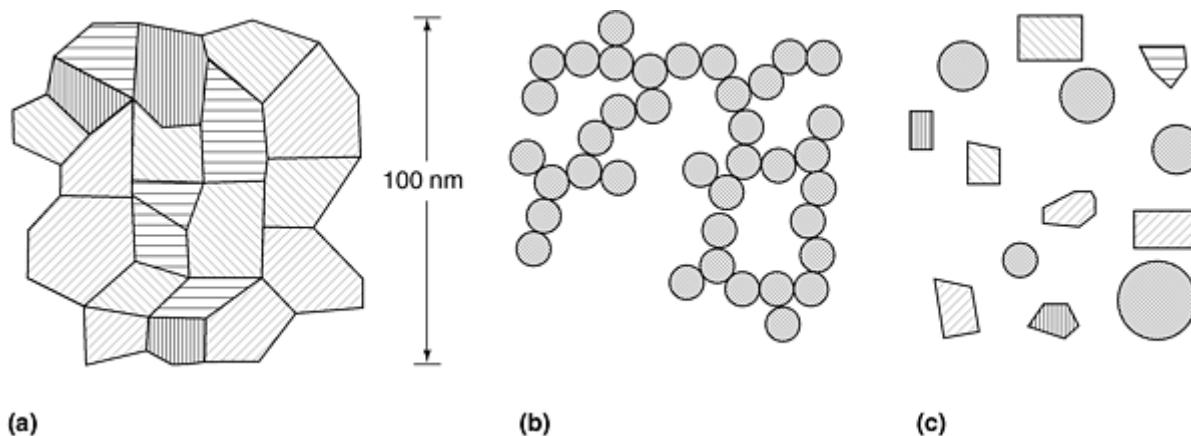

Fig. 11 Three different types of nanoscale materials: (a) nanocrystalline material, (b) agglomerated nanopowder, and (c) nanosuspension

Production Methods

The production techniques used for fine (micron scale) powders generally fail in the submicron (nanometer) range. Methods like gas or water atomization have a lower particle size limit of ~ 1 to $5 \mu\text{m}$. Milling is used for particle size reduction of very brittle materials like tungsten carbide or ceramics, but fail for ductile materials like precious metals.

A variety of methods are available for the production of ultrafine powders with submicron particle size. Gas phase reactions, spray drying, or precipitation methods are used most frequently. Thousands of tons of ceramic nanopowders have been produced for decades basically via thermal decomposition from the gas phase (aerosol process). One of the basic principles is the inert gas condensation (IGC). With IGC, high-quality powders with low chemical impurities from precursor materials, and low amounts of oxides or nitrides from the production process can be produced. Other principles like flame reduction or plasma reduction use the decomposition and reduction of metal salts in a gas flame or plasma. The chemical vapor reaction (CVR) process uses the reaction of metal chlorides and hydrogen in a hot wall reactor.

Table 7 gives a comparison of the most commonly used four basic methods in gas phase production of metal nanopowders. Information from approximately twelve companies active in production of metal nanopowders for industrial applications is the source of the different production techniques in Table 7. Additional companies are active in producing powders by liquid-phase techniques or by ball milling (Table 8).

Table 7 Comparison of the most frequently used gas phase methods for production of metal nanopowders

Method	Advantage	Disadvantage	Typical capacity
Flame reaction	Large output	Broad distribution of particle size, ionic impurities	>1 tonne/day
Plasma reaction	Large output	Broad distribution of particle size, ionic impurities	>1 tonne/day
Chemical vapor reaction	Narrow distribution of particle size	Ionic impurities	200 kg/day
Inert gas condensation	No impurities	Small output	<10 kg/day

Table 8 Overview on production processes used in industry

Production process	Number of companies (different processes possible)	Main products
Gas phase processes		
Inert gas condensation	4	Precious metals, Ni, Fe, Pt, semiconductor powders
Chemical vapor condensation	2	Ta and other refractory metals, semiconductor powders
Precipitation	3	Precious metals
Plasma or flame enhanced chemical vapor condensation	3	Mainly ceramics, side products are precious metals and others
Spray condensation	3	Carbides
Chemical precipitation in the liquid phase	5-10	Precious metals
Milling processes	~ 6	Carbides

The method used most frequently for the production of dry metal nanopowders with very low impurity content is based on the condensation of a supersaturated metal vapor in the presence of a nonreacting cooling gas such as helium. This method is described in more detail in the next section.

Inert Gas Condensation

The IGC method is performed by evaporating and condensing of the respective material in a vacuum cylinder filled with a low pressure of an inert gas (e.g., 10 mbar helium). Evaporation of the respective material can be completed by magnetron sputtering, electron beam, laser, or Joule heating of a crucible. The vapor nucleates homogeneously due to collisions with the cold inert gas atoms. The growth of particles within the convection gas flow occurs basically via coalescence. This type of growth process is intrinsic and leads to a Gaussian distribution of the resulting particle sizes on a logarithmic scale. The size of the primary particles that are agglomerated in a chain or network-like structure can be controlled via the type and pressure of the inert gas within approximately one to two orders of magnitude. Via thermophoretic effects, the particle fog condenses preferably on cooled substrates that are implemented into the container, for example, in the form of rotating stainless steel container filled with liquid nitrogen. The particles build up a flaky powder layer on the cooling wall and can be removed continuously by a scraper.

The fundamentals of the gas phase evaporation process are well understood and used for several process variations. Figure 12 shows the sketch of equipment used in a lab scale environment by Fraunhofer for production of precious metals nanopowders with a rate of ~ 1 to 2 kg/day.

Fig. 12 Sketch of pilot scale equipment to produce metallic nanopowders with the inert gas condensation technique. Source: Ref 14

Process Variations in Inert Gas Condensation. Several variations of the process exist, for example, evaporation in a reactive gas instead of an inert gas and formation of the respective nitrides or oxides of an evaporated metal. Other variations of the process are using an enforced gas flow transporting the particles to a porous substrate, where the particles are separated from the carrier gas. Additionally to these variations, the powder produced in the gas phase can be

deposited on different substrates depending on the planned application. Figure 13 shows the process variations possible for production of dry powder, dense pressed parts, dispersions, or filter applications.

Fig. 13 Process variation of the inert gas condensation for production of different types of nanoscale materials

Quality Affecting Factors in Production of Metallic Nanopowders. The main problems in production and processing are caused by the small particle size and the corresponding high specific surface area of nanopowders. As a main quality issue, the pickup of oxides or nitrides during processing or storage need to be prevented. As nanopowders are often used or processed in suspension, the degree of agglomeration is also a quality issue due to the need of deagglomeration of the powders. Both factors, the pickup of gaseous impurities and the agglomeration, increase with decreasing particle size. For nanopowders the development of technologies that integrate production and processing steps is essential.

Ultrafine and Nanophase Powders

Applications

Because of the very fine grain sizes, nanocrystalline materials exhibit a variety of properties that are different and often considerably improved in comparison with those of conventional coarse-grained polycrystalline materials. These properties include increased strength/hardness, enhanced diffusivity, improved ductility/toughness, reduced density, reduced elastic modulus, higher electrical resistivity, increased specific heat, higher thermal expansion coefficient, lower thermal conductivity, and superior soft magnetic properties in comparison with conventional coarse-grained materials. All of these properties are being extensively investigated to explore possible applications, and the origin and consequences of some of these properties are discussed in Ref 15.

Dense parts and porous coatings from ceramic nanopowders have attracted interest for decades, and many low-cost processing routes are available. In particular, the use of oxide nanopowders in optics, electronic, and cosmetics, (ultraviolet, UV, protection) is established. Several potential applications of metallic nanopowders are investigated and reported. The following two examples are typical for the use of nanopowders for functional materials.

Applications Based on the High-Sinter Activity of Metallic Nanopowders. With regard to solid state sintering theory and experimental proof, it is well known that a decrease in particle size enhances sinter activity and leads to intense shrinkage of pressed powders at temperatures well below those attained at conventional powder size. This property is particularly useful in electronic packaging technology, where electrically conductive bonding materials play an essential role. The cold welding properties combined with ductility make metal alloy nanopowders suitable sinter aids for metal to metal bonding. The high sinter activity can be usefully applied in diffusion bonding of parts. The nanopowders act as an intermediate layer. It was shown that after the bonding process no welding interface is visible in metallographic cross section.

In particular, sintering of ultrafine refractory metals provides a means to lower the sintering temperature. Due to the fact that the performance of tantalum capacitors is closely related to the specific anode surface area, the use of nanosized tantalum powders at a reduced sintering temperature was investigated (Ref 16). Figure 14 shows the decrease in sintering temperature obtained by use of 50 nm powder for tantalum capacitors compared with standard quality 2 μm powder.

Fig. 14 Decrease in sinter temperature of a tantalum nanopowder with decreasing particle size.

Source: Ref 16

Nanopowder-Polymer Composites for Microelectronic Applications. Metallic filling powders in polymers play an important role for the realization of electrical conductive adhesives, radio frequency shielding polymers, or magnetic polymeric layers. In most applications, the use of high-aspect ratio fibers and flakes is advantageous.

A reduction of the relative amount of metal powder in an electrical conductive adhesive or polymer is possible by using porous nanoscale powders (Fig. 15). With this reduction of filler volume, adhesives with a better thermo-cycling behavior can be produced for applications in automotive microelectronics (Ref 17).

Mechanical Alloying

C. Suryanarayana, Department of Metallurgical and Materials Engineering, Colorado School of Mines

Introduction

Mechanical alloying is a simple and useful technique to synthesize both equilibrium and non-equilibrium phases of commercially useful materials starting from elemental powders. It is also an economical process with important technical advantages. One of the greatest advantages of mechanical alloying is in the synthesis of novel alloys that are not possible by any other technique, such as alloying of normally immiscible elements. This is because mechanical alloying is a completely solid-state processing technique and therefore limitations imposed by the phase diagrams do not apply here.

Mechanical alloying (MA) is normally a dry, high-energy ball milling technique and has been employed to produce a variety of commercially useful and scientifically interesting materials. This technique was developed during the late 1960s by John S. Benjamin and his colleagues at the Paul D. Merica Research Laboratory of the International Nickel Company (INCO) essentially to combine the advantages of precipitation hardening and oxide-dispersion strengthening in several nickel- and iron-base superalloys (Ref 1, 2).

The formation of an amorphous phase by mechanical grinding of an yttrium-cobalt intermetallic compound in 1981 (Ref 3) and in the nickel-niobium system by ball milling of blended elemental powder mixtures in 1983 (Ref 4) brought about the recognition that MA is a potential nonequilibrium processing technique. Since the mid-1980s, a number of investigations have been carried out to synthesize a variety of stable and metastable phases including supersaturated solid solutions, crystalline and quasi-crystalline intermediate phases, and amorphous alloys. Efforts have been made since the early 1990s to understand the process fundamentals of MA. Additionally, it has been recognized that MA can be used to induce chemical (displacement) reactions in powder mixtures at room temperature or at least at much lower temperatures than normally required (Ref 5). This simple but effective processing technique has been applied to metals, ceramics, polymers, and composite materials. The important attributes of MA are:

- Production of fine dispersion of second phase particles
- Extension of solid solubility limits
- Refinement of grain sizes down to nanometer range
- Synthesis of novel crystalline and quasi-crystalline phases
- Development of amorphous (glassy) phases
- Disordering of ordered intermetallics
- Possibility of alloying of difficult to alloy elements
- Inducement of chemical (displacement) reactions at low temperatures

The different facets of MA have been reviewed periodically (Ref 6, 7, 8) and the literature available up to 1994 has been collected together in an annotated bibliography (Ref 9). Additionally, a number of conferences are devoted to the science and technology of mechanically alloyed materials and the proceedings of the annual International Symposia on Metastable and Mechanically Alloyed and Nanocrystalline Materials (ISMANAM) are regularly published in *Materials Science Forum* published by Trans Tech Publications, Switzerland.

Two different terms are used in the literature to denote the processing of powder particles in high-energy ball mills. Mechanical alloying describes the process when mixtures of powders (of different metals or alloys/compounds) are milled together. Material transfer is involved in this process to obtain a homogeneous alloy. On the other hand, milling of uniform (often stoichiometric) composition powders, such as pure metals, intermetallics, or prealloyed powders, where material transfer is not required for homogenization, has been termed mechanical milling (MM). Mechanical milling of ordered intermetallics has been shown to lead to disordering or amorphization, and the nature of these phase transformations and the reasons for their occurrence have been reviewed (Ref 10). Some investigators have referred to MM as mechanical grinding (MG). Since "grinding" is normally considered an abrasive machining process that involves mainly shear stresses and chip formation, the term *milling* is preferred because it includes the more complex triaxial, perhaps partly hydrostatic, stress states that can occur during ball milling of powders (Ref 7). It should be realized, however, that MA is a generic term, and some investigators use this term to include mechanical milling/grinding as well. This article uses the term MA only to include both MA and MM.

Mechanical Alloying

C. Suryanarayana, Department of Metallurgical and Materials Engineering, Colorado School of Mines

The Process of Mechanical Alloying

Figure 1 is a schematic showing the path of raw materials using the MA process. The raw materials, the type of mill used, the process of consolidation, and the details of heat treatment differ depending on the type of product desired, but the processing route remains essentially the same. It is possible that some minor steps are either added or deleted in some special circumstances. The actual process of MA starts with mixing of powders in the right proportion and loading the powder into the mill along with the grinding medium (generally steel balls). This mix is then milled for the desired length of time until a steady state is reached. A steady state occurs when the composition of every powder particle is the same as the proportion of the elements in the starting powder mix. Sometimes the powder is milled to an intermediate state either to form metastable phases or to achieve certain desired properties. The milled powder is then consolidated into a bulk shape and heat treated to obtain the desired microstructure and properties.

Fig. 1 Processing path in producing a product from powders by mechanical alloying. Source Ref 1

Raw Materials

The raw materials used for MA are widely available commercially pure powders that have particle sizes from 1 to 200 μ m. The powder particle size is not critical, except that it should be smaller than the grinding ball size, because the powder particle size decreases exponentially with time and reaches a small value after a few minutes of milling. These powders fall into the broad categories of pure metals, master alloys, prealloyed powders, and refractory compounds. The oxygen content of commercially pure metal powders ranges from 0.05 to 0.2 wt%. Therefore, if one is interested in studying phase formation, it becomes important to choose the proper purity of the powder. This is important because, more often than not, the nature and amount of impurities in the system decide the nature of the final phase formed and the chemical constitution of the alloy. Dispersion strengthened materials usually contain additions of carbides, nitrides, and oxides. Oxides are the most common and these alloys are known as oxide-dispersion strengthened (ODS) materials. In the 1960s, the powder charge for MA consisted of at least 15 vol% of a ductile compressibly deformable metal powder to act as a host or a binder. However, in the 1990s, mixtures of fully brittle materials have been milled successfully resulting in alloy formation. Thus, the requirement of having a ductile metal powder during milling is no longer necessary. Accordingly, ductile-ductile, ductile-brittle, and brittle-brittle powder mixtures are milled to produce novel alloys. Mixtures of solid powder particles and liquids have also been milled (Ref 11).

Process Control Agents

A process control agent (PCA) is added to the powder mixture during milling, especially when the powder mix involves a substantial fraction of a ductile component. The PCAs are mostly organic compounds, which act as surface-active agents.

The PCA adsorbs on the surface of the powder particles and minimizes cold welding between powder particles and thereby inhibits agglomeration. The surface-active agents adsorbed on particle surfaces interfere with cold welding and lower the surface tension of the solid material. Because the energy required for milling is equal to the product of new surface area generated times the surface tension, a reduction in surface tension results in the use of shorter milling times and/or finer powders.

A wide range of PCAs have been used in practice. These are mostly organic compounds used at a level of ~ 1 to 4 wt% of the total powder charge and include stearic acid [$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$], hexane (C_6H_{14}), oxalic acid [$(\text{COOH})_2 \cdot 2\text{H}_2\text{O}$], methanol, ethanol, acetone, isopropyl alcohol, heptane, Nopcowax-22DSP, octane, toluene, trichlorotrifluoroethane, DDAA (diodecyl dimethyl ammonium acetate), silicone grease, etc. Graphite, alumina, aluminum nitrate, and sodium chloride have also been used as PCAs. The majority of these compounds decompose during milling and interact with the powder and form compounds, which get incorporated in the form of dispersions inside the powder particles during milling. Thus, hydrocarbons containing hydrogen and carbon and carbohydrates containing hydrogen, carbon, and oxygen are likely to introduce carbon and/or oxygen into the powder particles, resulting in the formation of carbides and oxides that are uniformly dispersed in the matrix. These are not necessarily harmful to the alloy system because they can contribute to dispersion strengthening of the material. The hydrogen subsequently escapes as a gas or is absorbed into the metal lattice on heating or sintering.

Minimization or avoidance of cold welding of powder particles among themselves and to the grinding tools can also be achieved by other means. For example, the presence of air in the milling container acts like a PCA and prevents cold welding of the powders. Milling of the powders at very low temperatures (e.g., in liquid nitrogen) referred to as cryomilling also has been shown to minimize welding, probably due to the increased brittleness of the powder particles at such low temperatures. Metal powders (with face-centered cubic structure) milled in a hydrogen atmosphere have been found to become brittle and not stick to themselves or the container.

Some metals, such as aluminum, nickel, and copper, react with certain alcohols during milling to form complex metallo-organic compounds. For example, aluminum reacts with isopropyl alcohol. Other metals such as titanium and zirconium can react explosively with chlorinated fluids such as carbon tetrachloride. Chlorinated fluids should never be used with reactive metals. Reactive metals such as titanium and zirconium, when milled in presence of air, can pick up substantial amounts of oxygen and nitrogen and cause phase changes, including formation of new phases (Ref 12).

Reactive milling (milling of metal powders in the presence of reactive solids/liquids/gases enabling a chemical reaction to take place) has also been employed to synthesize metal oxides, carbides, and nitrides (Ref 13, 14, 15). Thus, milling of titanium in a nitrogen atmosphere has produced titanium nitride; several other nitrides have also been produced in a similar way. Milling of tungsten with carbon (graphite) has produced tungsten carbide. Milling of aluminum with carbon (or by use of a PCA containing carbon) produced aluminum carbide (Al_4C_3), which gets dispersed inside the aluminum matrix and improves the performance of the alloy. The carbide in this case formed only partially during milling; subsequent heat treatment was required to complete the reaction of carbon with aluminum. However, in other cases, the reaction can take place entirely during milling, only after heat treatment, or in part during both the stages.

The choice of a PCA for milling depends on the nature of the powder being milled and the purity of the final product desired. Use of a PCA normally introduces some impurities into the powder (see the section "Powder Contamination" at the end of this article). Thus, to produce a high-purity alloy, use of a PCA should be avoided. It should also be realized that there is no universal PCA. One would have to decide on a PCA looking at the possible interaction between the metal powder being milled and the components in the PCA.

Types of Mills

A number of mills are used to produce mechanically alloyed powders. They differ in capacity, efficiency of milling, and additional arrangements for cooling, heating, etc.

Shaker mills, such as SPEX mills (SPEX CertPrep, Inc., Metuchen, NJ) (Fig. 2a), which mill about 10 g of the powder at a time, are most commonly used for laboratory investigations and for alloy screening purposes. The common variety of the mill has one vial containing the sample and grinding balls, secured in the clamp and swung energetically back and forth several thousand times a minute. The back-and-forth shaking motion is combined with lateral movements of the ends of the vial so that the vial appears to be tracing a figure-8 or infinity sign as it moves. With each swing of the vial, the balls impact against the sample and the end of the vial, both milling and mixing the sample. Because of the amplitude (~ 5 cm) and speed (~ 1200 rpm) of the clamp motion, the ball velocities are high (~ 5 m/s), and consequently the force

of the ball's impact is unusually great. Therefore, these mills can be considered as high-energy variety. The most recent design of the mills allows for simultaneously milling the powder in two vials to increase the throughput. A variety of vial materials is available for the SPEX mills and these include hardened steel, alumina, tungsten carbide, zirconia, stainless steel, silicon nitride, agate, plastic, and methacrylate. A typical example of a tungsten carbide vial, gasket, and grinding balls for the SPEX mill is shown in Fig. 2b. Majority of the research on the fundamental aspects of MA has been carried out using some version of these SPEX mills.

Fig. 2 (a) SPEX 8000 mixer/mill in the assembled condition. (b) Tungsten carbide vial set consisting of the vial, lid, gasket, and balls. Courtesy of SPEX CertiPrep, Metuchen, NJ

The planetary ball mill (referred to as Pulverisette) is another popular mill for conducting MA experiments which allows a few hundred grams of the powder to be milled at a time (Fig. 3a). These are manufactured by Fritsch GmbH in Germany and marketed by Gilson Co., Inc. in the United States and Canada. The planetary ball mill owes its name to the planetlike movement of its vials. These are arranged on a rotating support disk, and a special drive mechanism causes them to rotate around their own axes. The centrifugal force produced by the vials rotating around their axes and by the rotating support disk act on the vial contents, consisting of material to be ground and the grinding balls. Because the vials and the supporting disk rotate in opposite directions, the centrifugal forces alternately act in like and opposite directions. This causes the grinding balls to run down the inside wall of the vial--the friction effect--followed by the material being ground and grinding balls lifting off and traveling freely through the inner chamber of the vial and colliding against the opposing inside wall--the impact effect (Fig. 3b).

Fig. 3 (a) Fritsch Pulverisette P-5 four-station ball mill. (b) Schematic depicting the ball motion inside the ball mill. Courtesy of Gilson Company, Inc., Worthington, OH

Even though the disk and the vial rotation speeds could not be independently controlled in the earlier versions, it is possible to do so in the modern versions. In a single mill one can have either two (Pulverisette 5 or 7) or four (Pulverisette 5) milling stations. Recently, a single-station mill was also developed (Pulverisette 6). Grinding vials and balls are available in nine different materials--agate, silicon nitride, sintered corundum 1, sintered corundum 2, zirconia, chrome steel, Cr-Ni steel, tungsten carbide, and plastic polyamide. Even though the linear velocity of the balls in this type of mill is higher than that in the SPEX mills, the frequency of impact is much higher in the SPEX mills. Hence, in comparison to SPEX mills, Fritsch Pulverisette can be considered lower energy mills.

Attritors are the mills in which large quantities of powder (from a few pounds to 100 lb) can be milled at a time (Fig. 4a). Commercial attritors are available from Union Process, Akron, OH. The velocity of the grinding medium is much lower (~ 0.5 m/s) than in Fritsch or SPEX mills, and consequently the energy of the attritors is low. Attritors of different sizes and capacities are available. The grinding tanks or containers are available either in stainless steel or stainless steel coated inside with alumina, silicon carbide, silicon nitride, zirconia, rubber, and polyurethane. A variety of grinding media also is available--glass, flint stones, steatite ceramic, mullite, silicon carbide, silicon nitride, sialon, alumina, zirconium silicate, zirconia, stainless steel, carbon steel, chrome steel, and tungsten carbide.

Fig. 4 (a) Model 1-S attritor. (b) Arrangement of rotating arms on a shaft in the attrition ball mill. Courtesy of Union Process, Akron, OH

The operation of an attritor is simple. The powder to be milled is placed in a stationary tank with the grinding media. This mixture is then agitated by a shaft with arms, rotating at a high speed of ~ 250 rpm (Fig. 4b). This causes the media to exert both shearing and impact forces on the material. The laboratory attritor works up to ten times faster than conventional jar mills.

Commercial mills for MA are much larger in size than the mills described above and can process several hundred pounds at a time. Mechanical alloying for commercial production is carried out in ball mills of up to 3000 lb capacity (Fig. 5). The milling time decreases with an increase in the energy of the mill. For example, a process that takes only a few minutes in the SPEX mill can take hours in an attritor and a few days in a commercial mill.

Fig. 5 Commercial production-size ball mills used for mechanical alloying. Courtesy of Inco Alloys International

Several new designs of mills have been developed in recent years for specialized purposes. These include the rod mills, vibrating frame mills, and the equipment available from Dymatron, Inc., Cincinnati, OH; Super Misumi NEV-MA-8 from Nisshin Giken, Co., Ltd., Tokyo, Japan (with the ability to control the temperature of milling from very low temperatures by spraying liquid nitrogen and up to 300 °C by electrical heating); Uni-Ball-Mill from Australian Scientific Instruments, Canberra, Australia (it is possible to control the nature and magnitude of impact of the balls in this machine with the help of magnets); HEMill from M.B.N. srl, Rome, Italy; and Zoz Maschinenbau GmbH, Kreuztal, Germany. The Uni-Ball-Mill with the spatially adjustable high field strength magnet (on the left side) that allows for continuously variable mill kinetics is shown in Fig. 6. Some special equipment is also designed for specific laboratory applications. The operating details and special features of these mills can be found in the respective brochures available from the manufacturers.

Fig. 6 Uni-Ball-Mill with the provision of a spatially adjustable high strength magnet. Courtesy of Australian Scientific Instruments, Fyshwick, Australia

Powder Handling

Mechanical alloying involves powders with very small sizes and these should be handled with caution and care. Because of the large surface area, they are highly reactive and can be pyrophoric and can cause health problems when inhaled. Precautions should be taken not to open the powder to atmosphere immediately after milling since this can lead to oxidation of the powders and in some situations they can even catch fire.

Mechanical Alloying

C. Suryanarayana, Department of Metallurgical and Materials Engineering, Colorado School of Mines

Mechanism of Alloying

During high-energy milling, the powder particles are repeatedly flattened, fractured, and rewelded. Whenever two steel balls collide, some amount of powder is trapped between them. Typically, around 1000 particles with an aggregate weight of ~ 0.2 mg are trapped during each collision. The force of the impact plastically deforms the powder particles, creates new surfaces, and enables the particles to weld together, which leads to an increase in particle size. In the early stages of milling, the particles are soft (using either ductile-ductile or ductile-brittle material combination) and their tendency to weld together and form large particles is high. A broad range of particle size develops, with some as large as three times bigger than the starting particles. The composite particles at this stage have a characteristic layered structure consisting of various combinations of the starting constituents. With continued deformation, the particles become work hardened and fracture by a fatigue failure mechanism and/or by the fragmentation of fragile flakes. Fragments generated by this mechanism can continue to reduce in size in the absence of strong agglomerating forces. At this stage, the tendency to fracture predominates over cold welding. Due to the continued impact of grinding balls, the structure of the particles is steadily refined, but the particle size continues to be the same. Consequently, the interlayer spacing decreases and the number of layers in a particle increases. As previously mentioned, the rate of refinement of the internal structure (particle size, crystallite size, lamellar spacing, etc.) is roughly logarithmic with processing time and therefore the size of the starting particles is relatively unimportant. In a few minutes to an hour, the lamellar spacing usually becomes small and the crystallite (or grain) size is refined to nanometer ($1 \text{ nm} = 10^{-9} \text{ m}$ or 10 \AA) dimensions (Fig. 7). The ease with which this can be achieved is one reason why MA has been extensively employed to produce nanocrystalline materials (Ref 8, 9, 16).

Fig. 7 Refinement of particle and grain sizes with milling time. Rate of refinement increases with higher ball-to-

powder weight ratios.

After milling for a certain length of time, steady-state equilibrium is attained when a balance is achieved between the rate of welding, which tends to increase the average particle size, and the rate of fracturing, which tends to decrease the average composite particle size. At this stage, each particle contains substantially all of the starting ingredients in the proportion they were mixed together, and the particles reach saturation hardness due to the accumulation of strain energy. The particle size distribution at this stage is narrow, because particles larger than average are reduced in size at the same rate that fragments smaller than average grow through agglomeration of smaller particles (Fig. 8). The average particle size obtained at this stage depends on the relative ease with which agglomerates can be formed by cold welding, fatigue and fracture strength of composite particles, and resistance of particles to deformation.

Fig. 8 Narrow particle size distribution caused by tendency of small particles to weld together and large particles to fracture under steady-state conditions

From the foregoing explanation, it is clear that during MA, heavy deformation is introduced into the particles. This is manifested by the presence of a variety of crystal defects, such as dislocations, vacancies, stacking faults, and increased number of grain boundaries. The presence of this defect structure increases the diffusivity of solute elements into the matrix. Further, the refined microstructural features decrease the diffusion distances. Additionally, the slight rise in temperature during milling further aids the diffusion behavior, and consequently, true alloying takes place among the constituent elements. While this alloying generally takes place nominally at room temperature, sometimes it may be necessary to heat treat the mechanically alloyed powder for alloying to be achieved. This is particularly true when formation of intermetallics is desired.

Mechanical Alloying

C. Suryanarayana, Department of Metallurgical and Materials Engineering, Colorado School of Mines

Consolidation

Widespread application of mechanically alloyed powders requires production of the powder in tonnage quantities and also efficient methods of consolidating the powders into bulk shapes. All the consolidation methods generally used in powder metallurgy processes can also be used for mechanically alloyed powders. However, because the powder particles in the mechanically alloyed condition are smaller (typically a few microns, even though the grain size may be only a few nanometers) in size than those used in conventional powder metallurgy operations, some special precautions need to be taken to minimize their activity and high level of interparticle friction.

Conventional consolidation of powder to full density through processes such as hot extrusion and hot isostatic pressing normally requires use of high pressures and high temperatures for extended periods of time. Unfortunately, this results in loss of the benefits achieved due to the metastable effects or nanostructures obtained by MA. Therefore, novel and innovative methods of consolidating the mechanically alloyed powders are required.

Mechanically alloyed powders have been consolidated into useful bulk shapes by several processes. Because mechanically alloyed powders have a high hardness, cold compaction is not an option. Further, ODS alloys have been found not to densify during simple sintering. The most common method of consolidation is hot compaction followed by hot extrusion, or by direct hot extrusion at temperatures greater than half the melting point. This process could be used if one is not concerned with the loss of metastable effects, such as the crystallization of the amorphous phase in the powder. Some of the consolidation methods used for mechanically alloyed powders, both on laboratory and industrial scales, include hot isostatic pressing, powder rolling, Ceracon processing, plasma activated sintering, electrodischarge compaction, and explosive forming (shock methods). These operations are usually carried out at temperatures considerably lower than those used for conventional powders. For example, while conventional γ -TiAl powders are hot isostatically pressed at about 1100 °C, mechanically alloyed γ -TiAl powders could be consolidated to full density by hot isostatically pressing them at about 750 °C.

Mechanical Alloying

C. Suryanarayana, Department of Metallurgical and Materials Engineering, Colorado School of Mines

Oxide-Dispersion Strengthened Alloys

Use of MA to synthesize metastable phases is a recent development. The major use of MA has been in the development of commercial ODS nickel-, iron-, and aluminum-base alloys.

Mechanically alloyed materials are strong both at room and elevated temperatures (Table 1). The elevated temperature strength of these materials is derived from more than one mechanism. First, the uniform dispersion (with a spacing of ~ 100 nm) of very fine (5 to 50 nm) oxide particles (commonly used are Y_2O_3 (yttria), ThO_2 (thoria), and La_2O_3 (lanthana)), which are stable at high temperatures, inhibit dislocation motion in the metal matrix, and increase the resistance of the alloy to creep deformation. Another function of the dispersoid particles is to inhibit the recovery and recrystallization processes, which allow a very stable large grain size to be obtained. These large grains resist grain rotation during high temperature deformation. A stable large grain size can also be obtained by secondary recrystallization mechanisms. The very homogeneous distribution of alloying elements during MA gives both the solid-solution strengthened and precipitation-hardened alloys more stability at elevated temperatures and overall improvement in properties. Mechanically

alloyed materials also have excellent oxidation and hot corrosion resistance. The increased resistance to oxidation-sulfidation attack is due to the homogeneous distribution of the alloying elements and the improved scale adherence due to the dispersoid itself (Ref 17, 18).

Table 1 Room temperature and elevated temperature mechanical properties of commercial ODS nickel-and iron-base superalloys (see Tables 2 and 3 for the chemical compositions of the alloys)

Alloy	Test temperature		0.2% Yield strength		Ultimate tensile strength		Elongation, %	Reduction in area, %
	°C	°F	MPa	ksi	MPa	ksi		
MA 6000	Room temperature		1220	177	1253	182	7.2	6.5

Commercial Processing of ODS Alloys

Commercial ODS alloys all use raw materials, such as elemental powders, crushed master alloy (intermetallic) powders, and prealloyed powders. Yttria powder lying within a narrow range of crystallite sizes (optimum strength of the alloy is achieved when the crystallite size is <30 nm) and metal powders are blended together to form a bulk preblend feedstock, the chemical composition of which is verified before actual processing starts. These ingredients are charged into large, horizontal axis ball mills containing alloy steel balls. Each ball mill is used for the production of one type of alloy. Cross contamination between different alloys is thus avoided, while pick-up from the through-hardened steel balls and the internal parts of the mill is prevented by the accumulation of a protective superalloy coating. During milling, an equilibrium powder particle size distribution is established and each individual particle acquires the alloying constituents in the correct proportions. The process is considered complete when the composite particles have a finely layered structure, not visible under an optical microscope.

The mechanically alloyed powder from the mill is then collected into stainless steel containers, and powder from several different containers (production runs) can be blended together at this stage. After a full chemical analysis, the blend is consolidated at elevated temperatures by either extrusion or hot isostatic pressing (HIP). In most cases extrusion is preferred because it is less expensive than HIP and contributes to the work necessary for secondary recrystallization. The powder is loaded into mild steel extrusion cans measuring up to 300 mm in diam and 900 mm in length and containing up to 280 kg powder. The powder is soaked for several hours in a furnace at the extrusion temperature, during which time homogenization of the powder and true alloying occur, if it has not already occurred during milling. Extrusion is carried out in commercial presses at temperatures, ratios, and speeds that are independent variables and material dependent. The ODS alloys have a very fine equiaxed submicron grain structure in the as-extruded condition. The mild steel from the extrusion cans is removed either by machining or by pickling. However, the consolidation process chosen depends on the properties, shape, and size required for the final mill product.

Once consolidated, the mechanically alloyed billets are worked to final shape, such as sheet, plate, bar, tube, etc., using normal hot working methods such as extrusion and hot rolling. Virtually all processing of the nickel-base alloy is performed hot, while cold working operations are possible with the iron-base alloys. This material is then subjected to a secondary recrystallization anneal at temperatures at or above 1300 °C to produce a coarse grain structure. The combination of oxide dispersion strengthening and coarse grain structure provides outstanding creep and stress rupture properties at elevated temperatures of >1000 °C.

Applications

The technique of MA has been shown to produce a variety of materials. The most important reason for the development of MA was the production of ODS materials in which fine particles of Y_2O_3 or ThO_2 were uniformly dispersed in a nickel-or iron-base alloy. In the mid-1980s, it was realized that MA is also capable of producing true alloys from elements that are not either easy to form by conventional means or sometimes even impossible to prepare, e.g., elements which are immiscible under equilibrium conditions. Investigations have revealed that metastable phases, such as supersaturated solid solutions, non-equilibrium crystalline or quasi-crystalline intermediate phases, and amorphous alloys, can be synthesized by MA (Ref 7, 8, 9). In addition, nanostructures with a grain size of a few nanometers, typically <100 nm, are produced. These metastable phases have interesting combinations of physical, chemical, mechanical, and magnetic properties and are being widely explored for potential applications. It is impossible to provide details of each of these developments, so only a very brief survey of the ODS alloys is presented here. Details of the structure and properties of metastable alloys are in Ref 7, 8, 9, and 10.

Ever since it was realized that MA could synthesize metastable phases, attempts have been made to compare the results of MA with those of rapid solidification, another non-equilibrium processing technique, even though the mechanisms by which metastable phases form by these two techniques are different. For example, solid solutions have been formed in the whole composition range in the copper-silver system by both techniques. A similar situation was obtained in several other systems by rapid solidification methods but not MA. Solid solutions have been obtained in the full composition range in the Cu-Fe, AlSb-InSb, and Cu-Co systems by MA but not by rapid solidification. Similarly, the levels of solid solubility achieved differ in various systems using the two techniques.

A similar situation exists with respect to the formation of metastable intermediate phases and amorphous alloys. Formation of an amorphous phase has been reported in the titanium-aluminum system by MA, which is not possible by rapid solidification methods. An important difference between these methods is that while amorphous phases form in the vicinity of eutectic compositions by rapid solidification, they form near the equiatomic composition by MA. Further, the glass formation range (the composition range over which glasses can form) is wider in the mechanically alloyed condition than in rapid solidification.

Formation of nanostructures has been reported in many alloy systems by mechanical alloying methods, but not by rapid solidification methods. But, devitrification of amorphous phases obtained by rapid solidification has led to the synthesis of nanostructure composites useful for magnetic applications (Ref 19).

Another important difference between mechanically alloyed and rapidly solidified alloys containing dispersoids appears to be in the size and distribution of the dispersoids. Figure 9 shows a pair of transmission electron micrographs comparing the matrix grain sizes, and size and distribution of dispersoids in HIP compacts of Ti_3Al -base alloys containing Er_2O_3 dispersoids. The rapidly solidified alloy was Ti_3Al to which 2 wt% Er was added and then hot isostatically pressed at 850 °C. The mechanically alloyed material was Ti-25Al-10Nb-3V-1Mo (at.%) to which 2 wt% Er was added and the alloy powder was hot isostatically pressed at 1000 °C. Even after HIP at a higher temperature, in comparison to the rapidly solidified alloy, the mechanically alloyed material showed a finer matrix grain size, more uniform distribution of the dispersoids, absence of large dispersoids at the grain boundaries, and absence of dispersoid-free zones near the grain boundaries.

Fig. 9 Transmission electron micrographs showing the difference in the matrix grain size, and size and distribution of dispersoids. (a) Rapidly solidified and hot isostatically pressed at 850 °C. (b) Mechanically alloyed and hot isostatically pressed at 1000 °C

The majority of these and other differences between materials processed by the two techniques could be traced to the fact that rapid solidification is a liquid-to-solid transformation while MA is a fully solid-state transformation.

The major industrial applications of mechanically alloyed materials have been in thermal processing, glass processing, energy production, aerospace, and other industries. These applications are based on the oxide-dispersion strengthening effect achieved in mechanically alloyed nickel-, iron-, and aluminum-base alloys.

Nickel-Base Alloys

Typical compositions of the commercially available mechanically alloyed nickel-base superalloys are presented in Table 2. The most significant advantage of oxide-dispersion strengthened superalloys is the increased stress rupture properties. Figure 10 compares the specific rupture strength (strength/density) for a 1000 h life as a function of temperature for several nickel-base superalloys used for turbine blade applications. Mar-M200 is a nickel-base alloy containing by weight percent 9.0 Cr, 5.0 Al, 2.0 Ti, 12.0 W, 10.0 Co, 1.0 Nb, and 1.8Hf, while PWA454 is a nickel-base alloy containing 10.0 Cr, 5.0 Al, 1.5 Ti, 12.0 Ta, 4.0 W, and 5.0 Co, and TD Ni is nickel containing 2.0 wt% ThO₂. It is clear from this figure that the MA 6000 alloy can maintain a given stress for a much longer time than a conventional alloy for similar vane applications. This is mainly due to the benefits of the combined strengthening modes in the mechanically alloyed material.

Table 2 Nominal compositions (wt%) of mechanically alloyed nickel-base superalloys

Alloy	Ni	Cr	Al	Ti	Mo	W	Y ₂ O ₃	Ta

The ODS alloys continue to find applications in a wide variety of industries. The two production facilities of Inco Alloys International have a combined annual powder capacity approaching 300,000 kg. The yield of the final product varies greatly with the product form and size, but the final wrought capacity is over 200,000 kg.

The mechanically alloyed superalloys are considered mainly for three groups of applications--gas turbine vanes, turbine blades, and sheets for use in oxidizing/corrosive atmospheres. The largest use of MA 754 is as vanes and bands for aircraft gas turbine engines (Fig. 11). For applications requiring good resistance to thermal fatigue, such as gas turbine vanes, Inconel MA 754 is given a strong texture. The majority of the grains are aligned so that their $\langle 100 \rangle$ axes are parallel to the principal working direction and along the length of the bar. Such texture results in low modulus of elasticity (149 GPa or 21.6×10^3 ksi) in the longitudinal direction. The low modulus improves resistance to thermal fatigue by lowering stresses for given thermal strains. Components are fabricated from bar stock using state-of-the-art machining and brazing processes typical for conventional wrought superalloys. Alloy MA 758 is used in a number of industrial applications where its high chromium content makes it resistant to extremes of temperature and environment. The alloy is used in the glass industry for high temperature components requiring both elevated temperature strength and resistance to extremely corrosive molten glass. Alloy MA 758 is also used for internal combustion engine components, mainly in critical fuel injection parts. One novel industrial application of alloy MA 754 is a high-temperature atmosphere-circulation fan in a "floating" furnace design being commercialized in Japan. Large rounds are used for the hub and plate material is used for blades of the fan, which operates at temperatures >1100 °C.

Fig. 11 Some typical gas turbine engine components made on INCONEL alloy MA 754. Courtesy of Inco Alloys International

New product forms of the commercial alloys continue to be developed. Large diameter, thin wall tubing of alloy MA 754 has been produced and evaluated for radiant tube applications, and alloy MA 758 has been used as tubing in heat exchangers and process equipment operating at very high temperatures.

The alloy MA 754 is used for brazed nozzle guide vane and band assemblies in U.S. military aero engines. The principal advantages of the alloy for these applications are thermal fatigue resistance, long-term creep strength, and high melting point.

The MA 6000 alloy is a more complex alloy developed as a blade material for advanced gas turbines. It is used for first and second stage turbine vanes and blades machined from solid bar. Unlike cast alloys, MA 6000 exhibits nearly flat rupture-life curves at high temperatures due to the combination of oxide-dispersion strengthening and high grain-to-width ratios (typically >10 to 1). Because of its composition, MA 6000 has excellent resistance to oxidation and sulfidation. The characteristics of this alloy allow blade cooling to be reduced or eliminated as the metal temperature can be increased by 100°C or more in engines where the stresses are medium or low.

Iron-Base Alloys

Table 3 lists the chemical compositions of mechanically alloyed iron-base superalloys. These alloys combine the high-temperature strength and stability of oxide-dispersion strengthening with excellent resistance to oxidation, carburization, and hot corrosion. These alloys are suitable for use in gas turbine combustion chambers. Incoloy alloy MA 956 is particularly well suited for use in heat processing applications. For example, vacuum furnace fixtures made of MA 956 have shown excellent durability and are able to compete with wrought molybdenum, which is also used in these applications. In comparison to molybdenum, MA 956 is $\sim 30\%$ lower in density, providing weight savings and cost advantages. Further, since MA 956 has a lower vapor pressure than molybdenum, it will not coat the inside of the vacuum chamber or the parts being heat treated. Thus, MA 956 rods, flats, and sheets are used in numerous atmosphere and vacuum furnace applications including muffles, baskets, trays, and thermowells. Alloy MA 956 in tubing form has also been used for high temperature, severe service applications such as coke injection lance pipes in steel making. The alloy MA 956 is also being used in the glass processing industry because of its resistance to attack by molten glass. Because of this corrosion resistance, the alloy is being evaluated for applications such as firing-kiln rollers, muffle tubes, and furnace racks. Other applications include molten-glass resistance heaters, thermocouple protection tubes, glass-processing components used in nuclear waste disposal, and the bushings used to make single and multistrand fibers.

Table 3 Nominal compositions (wt%) of mechanically alloyed iron-base superalloys

Alloy	Fe	Cr	Al	Ti	Mo	Y ₂ O ₃
INCOLOY alloy MA 956	bal	20	4.5	0.5	...	0.5
INCOLOY alloy MA 957	bal	14	...	1.0	0.3	0.25

More recently, MA 957 has been evaluated for use as the fuel cladding in fast neutron, breeder reactors. Conventional austenitic alloys are unsuitable for this application due to the dimensional swelling phenomenon caused by the high neutron fluxes. The mechanically alloyed materials are also being evaluated for heat exchanger components in high-temperature gas-cooled reactors. Figure 12 shows some typical high-temperature applications of the alloy MA 956.

The hearth legs are encased in alumina sleeves to prevent direct contact with the graphite heating elements. Courtesy of Inco Alloys International

Aluminum-Base Alloys

The success of mechanically alloyed superalloys led to the development of dispersion-strengthened aluminum alloys. Table 4 lists the compositions of the mechanically alloyed dispersion-strengthened aluminum alloys. Because an aluminum oxide layer is always present either on the surface of the powder particles at the start of processing or during milling, its incorporation into the alloy contributes to significant improvements in the properties of the alloy. Further, since aluminum is a ductile metal, PCAs are added to assist in minimizing cold welding during processing. Aluminum carbides are formed during MA by the decomposition of the PCA. Both the oxide or carbide type dispersions are approximately 30 to 50 nm in size and stabilize the ultrafine grain size. This results in a 50% increase in strength, higher fracture toughness, and improved resistance to stress corrosion cracking and fatigue crack growth of the mechanically alloyed materials. IncoMAP alloy AL-9052 has a density 5% less than that of conventional age-hardenable aluminum alloy of comparable strengths such as 2024. With its combination of lightweight, high strength, and corrosion resistance, IncoMAP alloy AL-9052 is evaluated for aerospace applications where marine corrosion is also a factor.

Table 4 Nominal compositions (wt%) of mechanically alloyed dispersion-strengthened aluminum-base alloys

Alloy	Al	Mg	Li	C	O
IncoMAP alloy AL-9021	bal	1.5	...	1.1	0.8
IncoMAP alloy AL-9052	bal	4.0	...	1.1	0.6
IncoMAP alloy AL-905XL	bal	4.0	1.3	1.1	0.6

Addition of lithium to mechanically alloyed aluminum alloys has produced an ultra lightweight alloy, IncoMAP AL-905XL. Its density is 8% lower and stiffness 10% greater than the age-hardenable conventional alloy 7075-T73 of comparable strength. The excellent combination of the properties makes this alloy very attractive for airframe applications. In particular, the freedom from age-hardening treatments makes it possible to produce forgings and heavy sections with homogeneous metallurgical structures.

Recently, high-strength aluminum-titanium alloys have been developed using MA by dispersing nanometer or submicron-sized Al_3Ti intermetallic particles (in addition to the Al_2O_3 and Al_4C_3 dispersoids from addition of PCAs) in an aluminum matrix. Similar approaches could be used to develop high strength alloys in other systems.

Magnesium-base Alloys

A useful application of the MA technique was in the production of supercorroding magnesium alloys that operate as short-circuited galvanic cells to corrode (react) rapidly and predictably with an electrolyte, such as seawater, to produce heat and hydrogen gas (Ref 20, 21). Such an alloy system is suitable as a heat source for warming deep-sea divers, as a gas generator to provide gas for buoyancy, or as a fuel in hydrogen engines or fuel cells. The corrosion rate of alloys can be maximized by providing (a) a short electrolyte path, (b) a large amount of exposed surface area, and (c) a strong bond (weld) between the cathode and the anode. It is also useful to provide a very low resistance path for external currents to flow through the corroding pairs. All these requirements can be met with MA processing. Consequently, magnesium-base alloys containing Fe, Cu, C, Cr, or Ti have been evaluated for such applications. The Mg-5 to 20at.% Fe alloy is ideal because of its extremely fast reaction rate, high power output, and the high percentage of theoretical completion of the actual reaction. For corrodable release links an alloy with a slower reaction rate, such as Mg-5at.% Ti is useful.

There have also been a number of investigations in recent years to examine use of MA to produce metal hydrides. This is because metal hydrides are materials for safe storage of hydrogen, and they can store hydrogen with a higher volume density than liquid hydrogen. However, these are sensitive to surface oxidation and hence can be a limiting factor in their commercial utilization. Nanocrystalline hydrides have a high density of defects and interfaces that could enhance diffusion; therefore, nanocrystalline intermetallics would not require activation treatments at high temperatures and pressures after exposure to air (Ref 22). In comparison to coarse-grained materials, mechanically alloyed nanocrystalline intermetallics exhibit a narrower absorption plateau and a lower plateau pressure. Their hydrogen storage behavior is typical of amorphous systems. Several magnesium-base and iron-base intermetallics are being evaluated for this application.

Displacement Reactions

Mechanical activation of solids to induce chemical reactions has been used for over 30 years (Ref 5). A resurgence in this activity occurred in 1989 when it was recognized that MA can be used as the basis of a chemical refining process (Ref 23) by demonstrating that the pure metal copper can be synthesized when CuO and calcium were ball-milled together at room temperature. Simultaneous reduction of CuO and ZnO by calcium has also been shown to result in the formation of β -brass. Metal synthesis directly from oxides or chlorides has now been extended to the synthesis of a number of metals (Zn, Ti, Zr, Ta, Gd, Er, Sm, V, W and some intermetallics, e.g. SmCo₅). A concise review on this subject is found in Ref 24.

Most of the reactions studied to date have been displacement reactions:

where a metal oxide (MO) is reduced by a reductant (R) to the metal (M). Metal chlorides have also been reduced to metals this way.

The displacement reactions studied by MA are characterized by a large negative free energy change at room temperature and are therefore thermodynamically feasible at room temperature. However, commercial operations by pyrometallurgical techniques are conducted at elevated temperatures to overcome the kinetic barriers and achieve sufficiently high reaction rates. Mechanical alloying can provide the means to substantially increase the reaction kinetics of the displacement reactions because the repeated fracturing and welding of powder particles increases the area of contact between the particles and allows fresh surfaces to come into contact repeatedly. This allows the reaction to proceed without diffusion through the product layer. Additionally, the high defect densities induced during MA accelerate the diffusion process. As a consequence, these reactions will now occur at room temperature. If a reaction cannot occur at room temperature, the particle refinement and consequent reduction in diffusion distances (due to microstructural refinement) can at least significantly reduce the reaction temperatures.

Depending on the milling conditions, two entirely different reaction kinetics have been noted. The reaction can extend to a very small volume during each collision between the grinding media leading to a gradual transformation. Alternatively, if the reaction enthalpy is sufficiently high, a self-propagating combustion reaction can be initiated. Such reactions require a critical milling time for the combustion reaction to be ignited. If the temperature of the powder (or milling vial) is recorded during MA, a sudden increase in temperature at a critical time indicates the onset of the combustion event. Measurements of the ignition time provide a useful means of characterizing the structural and chemical evolution during MA.

The product of the displacement reactions normally consists of two phases-the metal (or a compound) and the oxide or chloride associated with the reductant. The removal of the unwanted reaction by-product can be difficult due to the high reactivity of the metal phase associated with nanocrystalline grain sizes and intermixing of the phases induced by the MA process. The by-product phase can be easily removed if the metal particles are embedded in a continuous matrix. Removal of the by-product is achieved by leaching the product mixture in a dilute acid or hot water, or by vacuum distillation. The use of carbon or hydrogen as the reductant produces gaseous CO₂ or water vapor as the byproduct and obviates the need for leaching/distillation.

Process parameters such as milling temperature, ball diameter, ball-to-powder weight ratio, use of a process control agent, and relative proportion of the reactant phases seem to play an important role on the nature and amount of product phase obtained by the displacement reactions and these need to be optimized for the best yields.

The mechanically driven displacement reaction offers a number of advantages over conventional metal processing techniques. First, it enables the reduction of a number of oxides and halides to pure metals at room temperature, thus effecting energy savings. Second, if a number of components are reduced simultaneously, it is possible to produce an alloy without first having to convert the oxides to pure metals and then to the desired alloy. Third, for powder metallurgy applications, it allows the direct formation of powder product without first having to manufacture the bulk alloy and then convert it to powder form. Thus, a number of high-temperature processes can be combined into one single room-temperature process with the potential for significant cost savings.

Powder Contamination

A major concern in the MA process is the impurities that get into the powder and contaminate it. The small size of the powder particles, availability of large surface area, and formation of fresh surfaces during milling all contribute to the contamination of the powder. Thus, it appears as though powder contamination is an inherent drawback of the technique, unless special measures are taken to avoid/minimize it.

As mentioned earlier, in the early stages of MA, the metal powder coats the surface of the grinding medium and the inner walls of the container. This was expected to have prevented contamination of the powder and so no attention was paid to the problem of powder contamination. However, when different results were reported by different groups of researchers on the same alloy system, it was recognized that contamination could be a problem. This problem appears to be ubiquitous and is now encountered in many investigations, especially when reactive metals such as titanium and zirconium are milled. The magnitude of contamination appears to depend on the time of milling, the intensity of milling, the atmosphere in which the powder is milled, and difference in strength/hardness of the powder, and the milling medium. Whereas 1 to 4 wt% iron has been found to be normally present in most of the powders milled with the steel grinding medium, amounts as large as 7 wt% (20 at.%) iron in a tungsten-carbon mixture milled for 310 h and 13 wt% (33 at.%) iron in pure tungsten milled for 50 h in a SPEX mill were also reported. These are very high levels of contamination. Similarly, large amounts of oxygen (up to 36.5 at.%) and nitrogen (up to 22.6 at.%) have also been reported to be present in aluminum-titanium powders milled for 400 h in a low-energy ball mill.

Contamination of metal powders can be traced to chemical purity of the starting powders, milling atmosphere, milling equipment, and the process control agents added to the powders. Contamination from chemical purity can be either substitutional or interstitial in nature, while contamination from the milling atmosphere is essentially interstitial in nature and that from milling equipment is mainly substitutional, even though carbon from the steel equipment can be an interstitial impurity. Contamination from the PCA leads to interstitial contamination. The presence of interstitial impurities such as oxygen and nitrogen is deleterious to reactive metals like titanium and zirconium, and therefore maximum impurity levels are generally specified for acceptable microstructural and mechanical properties. Substantial amounts of nitrogen and oxygen (the amount of nitrogen is much higher than oxygen) are picked up during the milling of titanium and zirconium alloys and the presence of these impurities leads to a change in the constitution of the alloys (Ref 25, 26, 27). For example, the formation of an amorphous phase in titanium-aluminum alloys and a crystalline phase with a face-centered cubic (fcc) structure in powders milled beyond the formation of an amorphous phase have been attributed to the presence of large quantities of nitrogen in these alloys (Ref 12).

Several attempts have been made in recent years to minimize the powder contamination during MA. One way of minimizing the contamination from the grinding medium and container is to use the same material for the container and grinding medium as the powder being milled. In this case also there will be wear of the grinding medium and this gets

incorporated into the powder. Thus, even though there is no contamination, the chemistry of the final powder will be quite different from the starting powder; the metallic content (of the container and balls) would be higher than in the initial powder. This can be compensated for if we know how much of the metallic content is increased.

The above solution may be possible occasionally; but it is difficult in many cases due to the nonavailability of the special grinding medium and containers. The problem is becoming more and more complex because the technique of MA is being applied to a variety of materials, such as metals, alloys, ceramics, polymers, and composites, and it is impossible to get containers of all these types of materials. If a container of the same material to be milled is not available, then a thin adherent coating on the internal surface of the container with the material to be milled will minimize the contamination. If this is not possible, then a simple rule that could be followed to minimize contamination is that the container and grinding medium should be harder/stronger than the powder being milled.

The problem of milling atmosphere is serious and has been found to be the major cause of contamination in many cases. In fact, it has been observed that if the container is not properly sealed, the atmosphere surrounding the container, usually air (containing nitrogen and oxygen), leaks into the container and contaminates the powder. Thus, when reactive metals like titanium and zirconium are milled in improperly sealed containers, the powders are contaminated with nitrogen and oxygen. It has been reported that flushing with argon gas will not remove oxygen and nitrogen absorbed on the internal surfaces. Pickup of impurities during milling would reduce the pressure within the container allowing outside atmosphere to continuously leak into the container through an ineffective seal. In practice, it has been noted that if it is difficult to open the container lid due to the vacuum present inside, it is an indication that contamination of the powder is minimum.

Attempts have been made to improve the container seal integrity to prevent the outside atmosphere leaking inside. Use of high-purity argon (99.998%) atmosphere and improvements of the seal quality resulted in the processing of high-quality titanium alloy powder with as little as 100 ppm oxygen and 15 ppm nitrogen (Ref 26). This process, however, may not be economically viable and hence may not be feasible on an industrial scale.

It is also important to remember that cross contamination could occur if a container that was used earlier to mill some powder is used again to mill another powder without properly cleaning it.

The level of contamination can be different under different processing conditions and is dependent on the type of mill, intensity of milling, nature of the powder, nature of the grinding medium and container, ambient atmosphere, ball-to-powder weight ratio, seal integrity, and others. Claims have been made in the literature about the superiority of certain mills and practices over others, but systematic investigations on milling the same powder under identical conditions in different mills and evaluating the contamination levels have not been undertaken.

Modeling

From the previous description it is easy to realize that MA is a complex process. Like any other process, modeling of MA is carried out to identify the salient factors affecting the process and to establish process control instrumentation. By modeling the process effectively, it is possible to lower the number of actual experiments to be conducted to optimize the process and achieve a particular application.

The number of variables involved in the MA process is very large. For a particular alloy system, the variables include the type of mill, intensity of milling, type of milling media, ball-to-powder weight ratio, the atmosphere under which the powder is milled, purity of the powders, milling time, milling temperature, and nature and amount of the PCA used. These have a significant effect on the constitution of the powder. Even on a local scale, the nature of impacts between two balls, the frequency of impacts, and the amount of powder trapped between two balls during a collision could vary from point to point. Thus, modeling the MA process is a difficult task. In spite of this, some attempts have been made (Ref 28, 29, 30) and moderate success has been achieved in modeling the mechanics of the process. From the actual experiments conducted, attempts have been made to correlate the phases formed with the process parameters during milling. But, the ability to predict the final chemical constitution of the powder (type and description of phases formed) has not been achieved. It should be realized that due to the stochastic nature of the MA process, it is difficult to make absolute predictions.

Spray Drying and Granulation

Introduction

GRANULATION is a term used to describe two different types of processes. In one definition, granulation is the intentional agglomeration of fine particles into larger clusters to improve certain powder properties. For example, bulk powders typically have a low bulk density, do not readily flow, are dusty, and have low thermal conductivity. When properly granulated, the same powder pours easily, exhibits a high and uniform bulk density, does not experience dusting losses, and more efficiently transfers thermal energy. For example, in the case of a powder used as a feed material for high speed presses, the granules should typically be greater than 50 μm (2 mils), but less than 1000 μm (40 mils) in diameter, have a spherical shape, and should not be strong enough to retain their identity in the compacted part.

Granulation is also defined as the production of metal particles by agitating molten metal. The most commonly used techniques are spray drying and spray granulation. Another method is water granulation. These three methods are discussed in this article. Other granulation methods include agitation and pressure technique for ceramics (Ref 1).

Spray Drying and Granulation

Spray Granulation

Spray granulation (Ref 2) forms granules by atomizing a liquid or a binder solution into a fluidized powder bed (Fig. 1). Fluidization is achieved by directing a heated gas, which is usually air, through a distributor at the bottom of the powder

bed. The gas imparts a vigorous motion to the particles, which prevents the formation of large lumps. The binding liquid is usually sprayed into the powder bed with a two-fluid nozzle. Spray granulators can be designed to operate in either a batch or a continuous mode.

Fig. 1 Fluidized bed spray granulator. Source: Ref 3

The formation of granules in a spray granulator occurs through the random nucleation of small seed agglomerates, followed by the growth of these seeds to the desired size. Growth occurs either by the layering of powder onto the seeds or by the agglomeration of seeds to form larger granules. Granule growth by seed agglomeration forms irregular shapes.

Granule size increases as the fraction of the bed exposed to the binding liquid is reduced and as the spray nozzle is adjusted to give coarser droplets (Ref 3). Increasing the intensity of agitation of the bed (with a higher gas velocity) decreases the size of the granules. There is an upper limit on granule size because of the tendency of the powder bed to defluidize. However, spray granulation can form larger granules than is usually possible by spray drying because of longer residence times.

Spray granulation is commonly used in the pharmaceutical industry to prepare feedstock for tablet presses. It is used less frequently in the metal powder industry. However, both spray drying and fluid bed conversion are scaleable technologies and together provide the means for producing bulk quantities of nanophase composite powders at low manufacturing cost. A few examples of fluidized bed granulation are described below.

Metal Powder Granulation in a Plasma-Spouted/Fluidized Bed. A direct current (DC) plasma-spouted/fluidized bed was applied to the granulation of spherical alloy grains from metal powder mixtures. From a mixture of iron powder (149 to 210 μm) and aluminum powder (74 to 88 μm and 125 to 149 μm), alloy grains from 1 to 5 mm in diameter were obtained. The grains exhibited a dense homogeneous core and a porous nonhomogeneous shell structure. The grains were quite spherical; the average aspect ratio of the grains was >0.85 . The mass fraction of iron in the core section of product grains depended on the Al/Fe ratio of initial powder mixtures but was insensitive to the size of product grains and to the size of initial Al particles. Selective growth of seed grains was observed when sufficient seed grains were added to the starting powder mixture (Ref 4).

Contamination-Free Processing of Pyrophoric Rare Earths and Abrasive Ceramic Powders. The production of exactly limited particle fractions is an important process for rare earths (Sm-Co, Nd-Fe-B) and ceramic (oxides, carbides, nitrides, borides) products. Extremely fine products with tight upper particle size limits can be produced by a fluidized bed process (Ref 5). This allows practically wear- and contamination-free grinding of extremely hard products. The necessary grinding and classification can either be wet or dry, or a combination of both procedures (Ref 5).

Spray Drying and Granulation

Water Granulation

Water granulation is a process for producing coarse metal particles by pouring molten metals through a screen into water or by agitating molten metals into droplets with subsequent water quenching. Granulation of liquid metal offers a simple technique for solidification of metals, but pouring of liquid metal into water has always been regarded as hazardous. Nonetheless, several plants for granulation of steel and different kinds of ferroalloys have shown that granulation can be done in a safe and reliable way (Ref 6).

For example, granulation of ferrosilicon and Si-metal has a risk of explosions when done at high flow rates (Ref 6). The explosion potential is considered to be due to the rapid formation of steam. Light metals like ferrosilicon and Si-metal have a comparatively low falling velocity in the water and thus result in a high power generation per unit volume of water. To decrease the power concentration, the heated water has to be efficiently replaced, or the heat has to be distributed to a big volume. It has been found that the replacement of the water from a small cooling zone in a big water tank is rather difficult, but metal can be efficiently distributed over a big water surface to decrease explosion potential (Ref 6).

Another trial of water granulation of ferrosilicon was performed by impingement of molten alloy stream against stationary ceramic plate or rotary cone followed by water quenching of the drops. The test stand permitted variations of nozzle-plate/cone and plate/cone-water distances and adjustment of the inclination of the plate. Quality and size of the product was affected chiefly by the plate/cone-water distance. Better quality was obtained with impingement against rotary cone. Results provided the basis for development of an industrial-scale installation for granulation of ferrosilicon (Ref 7).

Spray Drying

Spray drying is a powder-producing process in which a slurry of liquids and solids or a solution is atomized into droplets in a chamber through which heated gases, usually air, are passed. Figure 2 represents a typical spray dryer utilizing a disk atomizer with co-current air flow. Examples of commercially spray-dried powders are shown in Fig. 3. Spray drying is used widely in the pharmaceutical, chemical, and food industries. It is used to a lesser extent in the metals-related industries.

Fig. 2 Typical spray dryer arrangement

Fig. 3 Micrographs of commercially spray-dried granules. (a) Ferrite, 75 \times . (b) Zirconia, 30 \times

Spray drying offers several advantages over other powder-processing techniques, particularly in applications requiring agglomerates for subsequent pressing and sintering operations. Spray drying also is one of the most economical ways of drying slurries.

Spray drying is a continuous rather than a batch process that allows close control of agglomerate size, bulk density, and moisture content. Agglomerate shape is spherical, facilitating excellent flowability. Particles have very short exposure time. Residence time within the dryer may range from 2 to 20 s, depending on dryer size. Therefore, heat-sensitive materials can be spray dried. Lubricating additives can be added easily for die pressing applications.

Process Description

During spray drying, atomized droplets dry rapidly because of their high surface-to-volume ratio. Coarse dried solids fall to the bottom of the chamber and are continuously collected, typically through a rotary airlock valve. The finer solids, which are entrained in the gases exiting the chamber, are removed by and collected from a cyclone separator. Baghouse collectors or wet scrubbers can be used to clean ultrafine particles from the air exhausted from the cyclone. Baghouse collectors and electrostatic precipitators also can be substituted for cyclone collectors. An alternate spray dryer design includes the introduction of the air through ductwork above the cyclone exit.

Size of the drying chamber is dictated by (a) product characteristics, (b) product throughput, (c) atomization technique, (d) the properties of the slurry or solution, and (e) the evaporative capacity of the heating unit and associated fans. The evaporative capacity is a function of the allowable inlet and outlet temperatures of the dryer. These temperatures are, in turn, dictated by the heat sensitivity of the product. The interrelationship of these factors is shown in Fig. 4 (Ref 8). Generally, a spray drying facility is designed as an integral unit so that all component capacities are compatible.

Fig. 4 Relationship between chamber volume and evaporation capacity of spray dryers. Data based on retention time of 20 s. Source: Ref 8

Some special applications in the cemented carbide industry require the use of organic solvents, such as acetone, ethanol, hexane, and methanol. Because of the flammable nature of these materials, close-system drying technology (see Ref 9, 10, 11) requires that the medium be spray dried using a nonoxidizing gas, such as nitrogen. By recycling the nitrogen that contains organic vapors, organic emissions are eliminated, and the solvent can be recycled.

Closed-cycle systems are gastight and operate slightly above atmospheric pressure. Most of the dried particles are collected from the dryer chamber; a small percentage of fines that pass through the chamber in the gas stream is collected in the cyclone.

The drying gas subsequently passes through a scrubber/condenser to recover the solvent and to recondition the nitrogen. Typically, gas temperature is controlled by a recirculating scrubber and heat exchangers that are cooled by water or brine. For some spray drying applications, a cooling system may be required.

Droplet-Air Mixing. The air flow pattern in the drying chamber controls the completeness of moisture removal from the droplet, the maximum temperature that the granules will experience, and the formation of wall deposits. Droplet-air mixing in spray dryers is determined by the location of the air disperser and the atomizing device and is classified

according to the relative direction between the droplets and the air. These classifications are termed cocurrent, countercurrent, and mixed-flow mixing.

Cocurrent conditions exist when the atomizing device is located near the air disperser at the top of the dryer, as in Fig. 5(a). The droplets are exposed to the hottest air immediately after formation, but high evaporation rates maintain low product temperatures. As the moisture content of the droplets decreases, they come into contact with cooler air and surface temperature does not increase appreciably. Cocurrent air flow is common in dryers equipped with rotary atomizers.

Fig. 5 Types of droplet-air mixing in spray dryers. (a) Cocurrent. (b) Countercurrent. (c) Mixed-flow. Source: Ref 12

In cocurrent drying, the maximum temperature to which larger dried particles are exposed is approximately 10 °C (18 °F) less than the outlet temperature of the dryer. This is caused by the evaporative cooling effect that occurs when the liquid leaves the droplet while passing through the heated zone. Finer particles, which dry more quickly, experience temperatures approaching those of the inlet gas.

Countercurrent conditions occur when the atomizing device is placed at the top of the chamber and the air disperser is located at the bottom (Fig. 5b). Immediately after formation, the droplets contact cool humid air. However, as their moisture content decreases, they are exposed to increasingly hotter air. Because high internal temperatures can be realized in the granules, the organic binders should not be heat sensitive.

When the slurry is introduced from the bottom and gas from the top of the dryer, droplets dry both in their upward and downward trajectories. Therefore, narrower, shorter dryers can be used. However, if partially dried products cannot be exposed to the high temperatures at the top of the dryer, this mode of spraying may not be applicable.

Mixed-flow conditions are a combination of cocurrent and countercurrent air flow. This type is commonly utilized in fountain-type dryers, where a nozzle atomizer is located at the base of the drying chamber and the air disperser is placed at the top of the chamber, as in Fig. 5(c). Mixed-flow conditions are frequently used in combination with pneumatic nozzles in small laboratory dryers because the fountain-like spray pattern increases droplet trajectory and provides sufficient airborne time to dry large droplets in small chambers.

Control of Powder Properties

Spray drying can be used to remove water from a slurry or to create agglomerates of fine particles contained within the slurry. Agglomeration is achieved by using a binder (discussed below in this section).

Most of the applications of spray drying in the metals industry require the formation of free-flowing agglomerates. Many of these powders are used for producing pressed parts. Therefore, the agglomerate size distribution and bulk density are the two most important properties of spray-dried powders.

Agglomerate size distribution is a function of atomization conditions and the properties of the slurry. Generally, a lower solids content yields a finer average agglomerate size. The maximum attainable solids content varies with material, but usually can be increased by using deflocculating or suspending agents.

Bulk density is a function of the solids content of the slurry, inlet temperature, and slurry additives. Lower bulk densities generally are achieved from slurries with low solids contents. Also, excessive inlet temperatures can cause lower bulk densities. Rapid evaporation of the liquids causes the partially dried droplets to expand rapidly, thus decreasing density. Introduction of frothing agents may entrap air in the slurry, which also leads to lower bulk densities. Typically, frothing agents are not added in metallurgical applications.

Moisture content of a powder can be controlled by the inlet and outlet temperature of the spray dryer in conjunction with the slurry feed rate. Moisture levels below 0.1% are possible. For a given airflow and inlet temperature, outlet temperature is controlled by the rate of slurry feed and the solids content. With higher percentages of solids, less water must be evaporated, which leads to higher throughput of dry product. If a product can withstand higher inlet temperatures, throughput can be increased (see Fig. 6).

Fig. 6 Relationship of evaporation capacity of spray dryers to production rate and slurry solids concentration.
Source: Ref 3

Binders for Agglomeration. Suitable binder materials must be homogeneously dispersable (preferably soluble) in the liquid used to form the slurry. When dry, binders must form a coating and/or adhere to the material being agglomerated. They must impart the required strength and crush resistance to the particle for subsequent handling. In addition to the liquid, solids, and binders used to formulate a slurry, various other additives may be necessary. The following are typical components of spray drying slurries:

Organic binders

- Polyvinyl alcohol
- Gum arabic
- Other natural gums
- Carboxy-methyl cellulose salts
- Polyvinyl acetate
- Methyl cellulose
- Ethyl cellulose
- Polyvinyl butyral dispersions
- Protein colloids
- Acrylic resin emulsions
- Ethylene oxide polymers
- Water-soluble phenolics
- Lignin sulfonates
- Propylene glycol alginates
- Flour
- Starches

Inorganic binders

- Sodium silicate
- Boric acid
- Borax
- Carbonates
- Nitrates
- Oxylates
- Oxychlorides

Plasticizers

- Glycerine
- Ethylene glycol
- Triethylene glycol
- Dibutyl phthalate
- Diglycerol
- Ethanolamines
- Propylene glycol
- Glycerol monochlorhydrin
- Polyoxyethylene aryl ether

Deflocculating agents

- Sodium hexametaphosphate
- Sodium molybdenate
- Tetrasodium pyrophosphate
- Ammonium citrate
- Ammonium oxalate
- Ammonium tartrate
- Ammonium chloride
- Monoethylamine

Wetting agents

- Synthetic detergents
- Alkylaryl sulfonates
- Alkylaryl sulfates
- Soaps

Suspending agents (high molecular weight)

- Sodium carboxymethyl cellulose
- Methyl cellulose
- Ethylene oxide polymers

Plasticizers may be used with binding materials that are hard or brittle and that tend to crack during drying. Suspending agents may be needed to prevent solids from settling within the slurry. Deflocculating agents aid in the formation of slurries by preventing the agglomeration of fine particles. Wetting agents also may be used to maintain solids in suspension. Some slurries have a tendency to foam during mixing. Antifoaming agents or defoamers may be used to control this action. Chemical activators also may be used as additives to aid in subsequent sintering or processing of powders.

Atomization Techniques and Agglomerate Size Distribution. Three standard techniques are used to atomize slurries for spray drying:

- Single-fluid nozzle atomization
- Centrifugal (rotating disk) atomization
- Two-fluid nozzle atomization

Table 1 gives the advantages and disadvantages of these techniques for atomization of slurries. Table 2 gives the relative agglomerate sizes produced by these techniques.

Table 1 Advantages and disadvantages of various spray drying atomization systems

Atomization system	Advantages	Disadvantages
Centrifugal (rotating disk)	High feed rates, less downtime, low-pressure pumps, never plugs	Larger diameter dryer required, coarse agglomerate size not obtainable
Single-fluid nozzle	Large agglomerate capability, smaller dryers can be used	Downtime due to part wear and plugging, high pressure pumps
Two-fluid nozzle	Less part wear	Broad agglomerate size distribution, compressed air needed

Table 2 Relative agglomerate sizes produced by various atomizing systems

Atomizing system	Mean agglomerate size, μm
Centrifugal (rotating disk)	
High speed	25-100
Medium speed	50-200
Low speed	100-300
Single-fluid nozzle	
High pressure	25-100
Medium pressure	50-200
Low pressure	100-300

Very low pressure	200-600
Two-fluid nozzle	
High pressure	10-50
Medium pressure	25-100
Low pressure	50-200

Source: Ref 12

As shown in Table 2, the largest agglomerate sizes (600 μm) are achieved by the single-fluid nozzle. The centrifugal (rotating disk) atomizer yields agglomerate sizes up to 300 μm , and the two-fluid nozzle produces agglomerates only up to about 200 μm in size. Centrifugal atomization yields the narrowest agglomerate size distribution range, followed by single-fluid atomization and two-fluid atomization.

Centrifugal atomization entails the introduction of the slurry into a horizontally rotating disk that is equipped with vanes or holes through which the slurry exits. The slurry is atomized into fine droplets, the average size of which is a function of the design and peripheral speed of the wheel. Most wheel designs incorporate a wear-resistant material for extended life.

Single-fluid atomization is capable of producing the largest diameter agglomerates. However, because of the high pressures required to force the slurry through a single, small orifice to produce the desired droplet size, considerable downtime may be required to replace worn parts and to unplug the nozzle. Use of a nozzle in the fountain spray position extends the residence time of the droplets in the chamber. As a result, smaller dryers can be used for single-fluid atomization of materials that are not heat-sensitive.

Two-fluid atomization, which uses a pressurized air blast to break up a slurry stream into droplets, produces the widest range of agglomerate sizes of all three atomization techniques. However, it is a relatively easy technique for producing atomized droplets. Wear problems do not exist because high pressures are not employed. The orifices used are typically larger than those used for single-fluid atomization; therefore, plugging is not as serve a problem. This technique does, however, require the use and additional expense of pressurized air.

Spray Drying and Granulation

Applications

Spray drying applications are most prevalent in the pharmaceutical, chemical, and food industries. There are, however, several areas in the metals industry that utilize spray drying techniques. These include production of cemented carbides, mineral processing, production of iron powders, production of oxide-dispersion-strengthened alloys, and production of powders used for thermal spraying applications.

Agglomeration by spray drying is a basic process that has unlimited possibilities in combining different materials to produce composite powders, which behave homogeneously in bulk. Investigations in producing custom-made powders have led to various multicomponent powders. The first step of this technique consists of the agglomeration of the starting powder, for example, metallic, oxide, and nonoxide hard materials. The second step includes plasma densification. Using the high energy of the plasma, materials with extremely high melting points can be melted.

Cemented Carbides (Tungsten Carbide/Cobalt). Historically, cemented carbides have been pressed from powders produced by various agglomeration techniques. With the advent of closed-cycle systems, production of cemented carbides by spray drying increased considerably in the 1980s. Closed-cycle spray drying is required for most cemented carbide powders because the binders that are used are soluble only in volatile organic fluids.

The nitrogen drying gas that is used in the spray drying of cemented carbides is heated to 75 to 100 °C (170 to 210 °F), depending on the milling liquid used. The solids content of the slurry varies from 75 to 80%. Viscosity of milled slurries is sometimes modified with stabilizers, such as stearic acid (0.3 to 0.5 wt%). Pressures for single-fluid nozzle atomization range from 590 to 1470 kPa (85 to 213 psi). Pressure is a function of the particular type powder, slurry viscosity, and binder content. Recent work related to spray drying for cemented carbides is described in Ref 13, 14, 15, 16, 17, 18, and 19.

Multicomponent Oxide Powders for Plasma Spraying. The concept of multicomponent powders consists of two steps. The first step is the agglomeration of the starting powder by the spray drying process. The second step involves plasma densification.

During spray drying, the starting powder combination is suspended in a liquid (water or solvent) and simultaneously mixed with binder and possible other needed auxiliary agents, for example, wetting agents, defoamers, etc. The suspension is sprayed through a nozzle into a heated chamber. Using rapid vaporizing, the formed droplets are dried briefly and micropellets are formed from the starting powder due to the adherence of the binder. This procedure and the properties of the resulting micropellets have certain advantages:

- There are almost no limits to the combination of different materials.
- Particle sizes of the micropellets are reproducible, dependent upon the process parameters.
- The starting components are homogeneously distributed in the micropellets.
- Nearly ideal spherical shape produces powders with excellent flowability.
- Lower energy consumption compared to other melting or crushing methods
- Easier control on mean diameter and size range

However, a key disadvantage of many spray dried powders is the poor mechanical resistance of the coating due to particle breakage (Ref 20). Particle breakage results in poor transport during the plasma spray coating process, which thus makes spray dried powder difficult to use for thermal spray. Fused and crushed powders are still the most widely used powder types for plasma spraying because they give deposits with good thermophysical properties and mechanical resistance.

To apply the advantages of spray dried powders for plasma spray coatings, a second step of plasma densification is required (Ref 20, 21, 22, and 23). In this step, the micropellets from spray drying are brought into a high energy plasma. Depending on the powder, one can choose whether the process takes place under atmospheric, inert atmospheric, vacuum, or underwater plasma spraying conditions. This additional step has the following advantages.

During plasma densification, reactions between the components of the micropellets occur, which during further processing, such as plasma spraying, leads finally to a more stable microstructure in the product. Without the plasma treatment, the reaction time is not sufficient, so the resulting metastable microstructure can lead to certain disadvantages and to property changes during use of the material.

Plasma densification enables high cooling rates so that disadvantages in microstructure--brittle phases or the solutioning of important phases--will not occur. This is an important advantage in contrast to conventional melting processes.

The plasma densified powder obtained has a spherical, smooth surface, a high density, and a porosity approaching zero. Experience in this technique concerning the plasma densification of metals, metallic hard materials, and ceramics shows that the multicomponent powder conception is practicable for nearly all materials. To characterize the properties, plasma

sprayed coatings of plasma densified powders were investigated. Results revealed that coatings of plasma densified powders show better resistance to wear than coatings of agglomerated powders.

Rotating Electrode Process

Steven A. Miller, Starmet Corporation, and Peter R. Roberts, American Superconductor

Introduction

THE ROTATING ELECTRODE process is a method for producing metal powders where the end of a metal bar is melted while it is rotated about its longitudinal axis. Molten metal is centrifugally ejected and forms droplets that solidify to spherical powder particles. The basic process is shown in Fig. 1. The electrode can be melted by any energy source, but usually an electric arc or plasma is used and the process is then identified by the acronyms REP or PREP, respectively. In this article REP is used generically unless a distinction needs to be made between the two processes. The REP concept was first invented by Starmet Corporation (then Nuclear Metals, Inc.), and resulted in the granting of patents (Ref 1, 2). While Starmet remains the sole source of REP/PREP (REP and PREP are registered trademarks of the Starmet Corporation) powder, powders are also made in Russia, China, and Japan using similar rotating electrode technology.

Fig. 1 Schematic of REP

The rotating electrode process has several inherent characteristics that make it uniquely suitable for the fabrication of specific alloy powders to provide manufacturing and product advantages. First, REP is a means of contactless melting and atomization to make powder with the highest level of cleanliness possible. This is a critical feature for reactive, high-melting-temperature alloys that are aggressively corrosive in their molten state and attack conventional ceramic crucibles. Such alloys are routinely atomized by REP without incurring contamination. Examples are titanium, zirconium, molybdenum, and vanadium alloys. Second, REP powder is almost perfectly spherical and practically satellite free. Because the atomized droplets are dispersed and move radially away from each other there is little opportunity for collisions between droplets and particles and the resulting coalescence of the two into irregularly shaped clusters. This single-particle nature of the powder spheres results in REP powder being very free flowing and having a high packing density, approximately 65%. Also, REP powder has both a tighter size distribution and a larger median size than can be produced by gas atomization. Finally, because REP atomization is produced by centrifugal forces rather than by aerodynamic drag, the powder is essentially porosity free when compared to gas atomized powder (Ref 3).

The rotating electrode process has evolved to include equipment that consists of a vacuum/controlled-atmosphere tank 2440 mm (96 in.) in diameter by 300 mm long in which powder is produced. The tank dimensions are determined by the trajectory and solidification distance of the largest droplets of the molten spray. This is mounted with its circular plane section in the vertical position. Figure 2 shows a typical production setup. The consumable rotating electrode is introduced through a seal-and-bearing assembly; the long axis of the electrode is horizontal and centrally located in the tank and is made the anode of a direct-current power circuit. The permanent cathode may be a simple tungsten-tipped

device provided with adequate cooling (REP) or a transferred arc plasma torch (PREP). This equipment projects through the other face of the tank to oppose the rotating electrode. Usually, melting is conducted under inert gas; the preferred medium is helium, which offers improved heat transfer properties and electric arc characteristics.

Equipment

There are two standard types of machines used in REP: short bar and long bar.

Short-Bar Apparatus. The short-bar machine (Fig. 3) accepts consumable anodes up to 89 mm ($3\frac{1}{2}$ in.) in diameter by 250 mm (10 in.) long. The anode is held in a collet in a precision spindle, the head of which projects into the tank through a rotating seal mechanism.

Fig. 3 Short-bar PREP

Usually at least 80% of the length of a short bar is converted to powder. Electrode stub removal and the introduction of new electrodes to the collet is performed manually through a glove port that is located in the front of the machine adjacent to the cathode or plasma torch. Short-bar methodology is appropriate for converting experimental quantities of material, alloys that are inherently brittle, and materials that have a low specific stiffness where an electrode of long aspect ratio is not practical.

Long-Bar Apparatus. Increased productivity and conversion efficiency are realized in the long-bar operation (Fig. 4), which is designed to consume 63.5 mm ($2\frac{1}{2}$ in.) diam electrodes that are up to 1830 mm (72 in.) long. Typically the assembly includes a precision spindle similar to that used in the short-bar machine. Instead of being fixed in position relative to the tank, the spindle is mounted on a table that also carries the drive motor and the electrical transfer brush mechanism. The table moves toward the tank from an extended starting position, feeding the electrode through the special seal-and-bearing assembly.

Fig. 4 Long-bar PREP

When the head of the spindle approaches the seal housing, the process is interrupted while the stub of the consumed electrode, now typically 230 to 250 mm (9 to 10 in.) long, is pushed through the seal by another long bar that is mounted in the spindle head when it is retracted to the starting position. Stubs produced in long-bar machines may be joined to new bars to obtain effectively 100% conversion to powder.

The rotational speed used is determined by the desired particle size. Standard speeds range between 314 rad/s (3000 rpm) and 1570 rad/s (15,000 rpm). Smaller diameter short-bars have been rotated up to 2620 rad/s (25,000 rpm). Because high-speed rotation rates are employed, electrodes must have precise dimensions; they must also be straight to keep mechanical out-of-balance forces to a minimum.

Rotating Electrode Process

Steven A. Miller, Starmet Corporation, and Peter R. Roberts, American Superconductor

Particle Size Distribution

Accurately controlled and maintained rotation speed of the anode is necessary to obtain a desired range of particle size distribution. Molten droplet diameter of a given material is determined by the properties of the liquid metal, the centrifugal ejecting forces (related to rotation speed), and to a limited extent the aerodynamics of the droplet trajectory through the inert cover gas. The following equation predicting median droplet size is obtained from a force balance of the centrifugal forces acting on the molten surface tending to cause atomization with the surface tension forces resisting atomization:

$$d = \frac{0.000346k}{\omega} \sqrt{\frac{\gamma}{\rho D}} \quad (\text{Eq 1})$$

where d is the median droplet diameter (microns); ω is rotation rate (rad/s); γ and ρ are the surface tension (dynes/cm) and density (g/cm^3) of the alloy being atomized, respectively; D is the electrode diameter (cm); and k is an empirical constant principally determined by the method of droplet formation which is in turn controlled by the melting rate (Ref 4). For any particular alloy, the material properties are fixed and Eq 1 can be further simplified to:

$$d = \frac{K}{\omega\sqrt{D}} \quad (\text{Eq 2})$$

where K is a constant (over a limited melting rate range) that has been determined for many alloy systems (Ref 5).

Figure 5 shows the powder size distributions of 1018 steel and Ti-6Al-4V produced at different rotational speeds. Within the steel data there is a clear reduction in particle size produced with increasing rotational speeds as predicted by Eq 1 and 2. Equation 1 also predicts that Ti-6Al-4V, due to its decreased density (approximately 57%) and increased surface tension (approximately 107%) compared to 1018 steel, would have greater inherent resistance to centrifugal atomization. Again, the data of Fig. 5 confirm the trend of the prediction, although the magnitude of the shift in sizes due to the change in melt properties is actually greater than that predicted by Eq 1.

Fig. 5 Effect of rotational speed and alloy properties on particle size

High-speed video images of the commercial REP process have shown the powder is formed by direct droplet production; that is, the liquid metal forms discrete droplets, with little or no ligament formation, as soon as it detaches from the bar surface (Fig. 6). Spheroidization of the liquid is nearly instantaneous; droplets tend to come off in clusters of stringers, and the droplet flight path is nearly tangential to the bar surface (Ref 6).

Fig. 6 High speed video of the droplet formation process. Instabilities formed in the liquid metal foil grow into ligaments, which ultimately separate into primary and secondary molten droplets

Champagne and Angers (Ref 7, 8) have demonstrated that a bimodal number distribution of particle size occurs due to this mechanism in which liquid drops separating from the electrode rim remain connected momentarily by a necked-down column of liquid metal that breaks into smaller drops when the major spheroid is freed. Bimodal particle size distribution is shown in Fig. 7. Although smaller particles are not present in large quantities by weight, their absolute numbers may be significant. This behavior is superimposed on distributions and is shown as a function of anode melting rate (Fig. 8) and rotation rate (Fig. 9).

Fig. 7 Bimodal particle size distribution attributed to satellite drop formation

Fig. 8 Particle size distribution as a function of melting rate

Fig. 9 Particle size distribution as a function of rotation rate

The ordinate values of these curves are expressed in terms of the percentage of retained particles on a given sieve size divided by the size range between sieves, which eliminates the effect of this range on the shape of the curve. Additional information can be found in Ref 7 and 8.

Aerospace Applications

Spherical metal powders made by REP or by gas atomization are not well suited for cold pressing into green compacts. Therefore, spherical powders tend to be used in specialized applications where consolidation is achieved by hot isostatic pressing (HIP), or other high-temperature processing in which interparticle voids are more readily closed. These particles flow well into complex mold shapes and can be tapped to a reproducible density of packing to provide fully dense parts that closely approach the dimensions of the finished component (Ref 9).

Much research has been performed on near-net shape compaction for military airframe parts in titanium alloys. An example of a complex shape that can be made from titanium alloy powders pressed to near-net shape is shown in Fig. 10. Overseas research has resulted in as hot isostatically pressed PREP superalloy powder being used in both land- and air-based gas turbines (Ref 10, 11). This use of powders can offer both economic and metallurgical advantages. Near-net-shape technology ensures more efficient material utilization, which is important for high-cost materials such as titanium. Additionally, the metallurgical benefits include improved homogeneity and control of microstructure to achieve enhanced mechanical properties (Ref 12).

Fig. 10 Gas turbine engine compressor rotor made from hot isostatically pressed plasma rotating electrode processed Ti-6Al-4V powder

Because REP prevents contact of the melted alloy with any container material, it provides a decided advantage over other methods of making contamination-free spherical particles. This process generates powder with cleanliness and composition approximating that of the precursor electrode. Molten titanium is extremely aggressive and reacts with all container materials; consequently, REP is ideally suited for production of clean titanium alloy powders in commercial quantities. Typical characteristics for Ti-6Al-4V powder made by REP are shown in Table 1.

Table 1 Typical Ti-6Al-4V REP powder compositions and properties

Element	Composition, wt%
Aluminum	5.50-6.75
Vanadium	3.50-4.50
Oxygen^(a)	0.13-0.20
Oxygen^(b)	0.05-0.13

Tensile tests conducted on hot isostatically pressed Ti-6Al-4V compacted from samples of rotating electrode processed powder indicate excellent properties, as shown in Table 2. Subsequent improvements in the process, which included plasma torch melting, have provided plasma rotating electrode processed Ti-6Al-4V P/M compacts with fatigue properties that are comparable or superior to those for cast and wrought materials. More recent work has demonstrated that plasma rotating electrode processed Ti-6Al-4V compacts generally have a narrower fatigue distribution than other forms. This allows design engineers to work with minimum property values in advanced aerospace structures. Careful control of cleanliness is critical to obtain this type of performance.

Table 2 Typical tensile properties of hot isostatically pressed Ti-6Al-4V rotating electrode processed powder

Orientation	Tensile strength		0.2% offset yield strength		Elongation (4D), %	Reduction in area, %
	MPa	ksi	MPa	ksi

Note: Consolidated material made by HIP at 950 °C (1750 °F) for 10 h at 100 MPa (15 ksi). Vacuum annealed for 10 h at 700 °C (1300 °F). Hydrogen after vacuum annealing equals 0.0057%.

- (a) Minimum.

The nonmetallic inclusions that occurred in early developmental work were associated with the initiation of fatigue failures in compacted pieces made from these materials. This problem has been eliminated by ensuring that the overall powder-making and handling process is designed so that foreign particles are excluded. As atomized powder is removed from the plasma rotating electrode machine under inert gas cover in closed collection vessels and is subsequently passed through a processing tower located within a class 100 clean room. This assembly sieves and passes particles whose sizes lie within desired upper and lower limits, and extracts a representative sample from a given lot of powder prior to loading

into appropriate containers. The entire powder processing tower can be evacuated and backfilled with inert gas. The overall system is shown schematically in Fig. 11.

Fig. 11 Ultraclean powder generation and clean-room processing

Ti-6Al-4V powder is also being used for the production of continuously reinforced metal-matrix composites. In one approach the powder is mixed with organic binders and cast as a thin tape. The tapes are then alternatively laid up with layers of continuous silicon carbide fibers and hot pressed to form a sheet. An alternative technology involves the plasma spraying of the titanium alloy powder directly onto the fibers to produce reinforced foils.

Other Powder Applications

Although REP and PREP are ideally suited to the production of clean powders for subsequent consolidation to fully dense parts, there are other applications for spherical metal particles. Wide application has been found for low-carbon steel powder in photocopier and printer applications, where rotating electrode processed spherical powder acts as a carrier for carbon black used in the printing cycle. In this application, the required particle size distribution is narrow enough so that the ability to optimize yields in the desired size range has made REP an attractive method for powder generation.

Because of their excellent flow characteristics, REP titanium, nickel-base, and high-alloy powder are being used in laser welding, repair, and enhancement of aircraft turbine parts. The same alloy powders are also being employed in the development of new free-form fabrication techniques (see the section "Laser-Based Direct Fabrication" in the article "Powder Metallurgy Methods for Rapid Prototyping" in this Volume).

Coarse particles in narrow size ranges meet unique medical needs. Cobalt-chromium alloys and titanium alloys are vacuum sintered or plasma sprayed onto the stems of prosthetic devices to form porous coatings. The porous structures so generated promote part fixation by bone ingrowth. In addition, the finer size ranges are used for consolidation to near-net shape for various implanted prostheses.

Rotating Electrode Process

Steven A. Miller, Starmet Corporation, and Peter R. Roberts, American Superconductor

Recent Process Development

Rotating electrode processed powder has been typically used for applications requiring a large median size (in excess of 100 μm). New product and manufacturing approaches require REP powder characteristics, but with maximum sizes being less than 100 μm (aerospace) and 44 μm (metal injection molding). In order to meet these needs two new approaches have been investigated to extend REP capability. Two modifications to the REP process have been developed for the production of finer powders.

The first, liquid argon quenching (LArQ) involves impact of the molten REP droplets with a high-velocity film of liquid argon. While balance issues limit rotational speeds to approximately 625 rad/s, for brittle alloys that cannot be rotated faster, LArQ produces almost a 5 to 1 decrease in median particle size (Ref 14).

The second, involves the close-coupled gas atomization of the molten REP-produced droplets. As the droplets formed by REP are being ejected from the electrode surface they are hit by a high-velocity gas jet. The aerodynamic drag imposed on the droplets causes further subdivision and atomization of the droplets. The atomization process is driven by aerodynamics, REP simply provides a means of injecting the liquid metal into the gas flow. This approach allows the melt and the gas flow to be close coupled for reactive alloys, maximizing the atomization efficiency. Close coupling has already been shown to provide substantial yield improvement compared to remote atomization for conventional alloys. Yields of Ti-6Al-4V powder are shown in Fig. 12, with large gains being made in the -44 and -100 μm yields (Ref 15).

Fig. 12 Comparison of power yields produced by REP alone and gas-assisted REP

Blending and Premixing of Metal Powders and Binders

Revised by Thomas Chirkot, Patterson-Kelley Co., Division of Harsco Corp.

Introduction

BLENDING OF POWDERS is defined as the thorough intermingling of powders of the same nominal composition. The implication with blending is that the constituents in the vessel are virtually identical except for some minor physical characteristics. For example, one may be interested in blending several lots of powder that have slight variations in moisture or color. Premixing is the preparation of a uniform mixture of two or more components. The implication with mixing is that the constituents in the vessel are different. They may differ in chemical composition or may be physically dissimilar. Many properties of powders and sintered parts--such as powder flow, apparent density, ejection stress, delubrication behavior, dimensional change, and mechanical strength--are quite sensitive to even small changes in particle size distribution and to fluctuations in the concentrations of components within a powder mixture.

In many cases, the P/M parts producer is interested in relatively large, uniformly blended powder lots, because costly and time-consuming process adjustments, often of an empirical nature, must be made. Adjustments are often made from lot to lot, even when the various lots are within given specifications.

Lubricated, single-component metal powders comprise the most important two-component systems in powder metallurgy. Important three- and four-component systems include iron-carbon-lubricant, copper-tin-lubricant, iron-copper-carbon-lubricant, and copper-tin-carbon-lubricant. The widespread use of powder mixtures rather than prealloyed powders is

attributable to both economic and technical factors: powder mixtures often are less expensive, have better compacting properties, and sometimes permit shorter sintering times.

Blending and Premixing of Metal Powders and Binders

Revised by Thomas Chirkot, Patterson-Kelley Co., Division of Harsco Corp.

Blending and Premixing Variables

The degree by which the formulation components differ governs the amount of energy needed to produce adequate results. From an economic perspective, it is important to understand the mechanisms of powder movement.

Mixing can be divided into two categories, random and ordered. Random mixing straddles the fine line between the definition of blending and mixing. In this category, the physical characteristics in the batch constituents are similar. This similarity allows the movement of the mixing vessel to be controlled by the laws of probability.

For these laws to be truly operative, the walls of the mixing vessel must have only a minimal influence on particle motion. A horizontal drum mixer is an example of a machine where wall interaction is simple. More complex vessel shapes can only be described by differential equations that characterize the system. Although significant investigation has gone into random mixing, the exercise is mostly academic because the conditions of true random behavior are generally not encountered in an industrial environment.

With ordered mixing, differences in the physical characteristics become important. In fact, these differences may have a favorable influence on mixing behavior. The ordering process is achieved by several factors acting individually or in concert. Mechanical ordering is caused by movement of the vessel. The ordering may be due to a tumbling-induced movement causing a splitting and merging of powder as the vessel rotates, or the movement may be augmented by baffles.

Properties of the materials also contribute to ordering. A rough-surfaced particle may trap smaller particles. Moisture within a particle may contribute to capillary attraction. On the molecular level, electrostatic and van der Waals attractions may be important.

Diffusion, convection, and shear are generally recognized as the most common mixing mechanisms. The diffusive mechanism is a particle phenomenon where vessel motion allows particles to redistribute themselves through contact with other particles or by dropping into a newly created void space.

The convective mechanism deals with groups of particles. Convective cells are induced within the mixer through agitation of the powder bed. Within a cell, the diffusive mechanism may also be operating. The shear mechanism creates slip planes with the bed and can cause substantial particle degradation.

These mechanisms exist on an energy continuum extending from the low-energy environment of diffusion to the high-energy environment of shear. Thus, the economic importance of defining the degree of uniformity of blending needed for each particular application is obvious.

Most types of mixing equipment achieve their highest degree of particle distribution rather quickly when dealing with dry, free-flowing, noncaking materials. Any extension of the mixing cycle usually results in a plus or minus variation from some acceptable mixing norm. Therefore, it is prudent to determine the minimum processing time needed to achieve the desired result and to terminate processing at that time.

Control over mixing time becomes more important when using higher-velocity mixing devices, in which particle fragmentation can introduce severe changes in particle behavior and a tendency toward segregation. Although the determination of minimum or optimum mixing is usually done by measuring specific technological powders properties as a function of time, a general method based on measuring the uniformity of a mixture follows.

The quality of a powder mixture improves as the number of contacts between the different components of the mixture increases. Figure 1 schematically illustrates various powder dispersions. A truly ordered particle arrangement (Fig. 1a) is

a theoretical standard. The ordering may be ephemeral if no adhesional properties are operating to maintain order. The agglomerated (Fig. 1b) and the demixed or segregated (Fig. 1d) arrangements represent extreme and undesirable particle dispersions. From a practical point of view, the statistical distribution of the components (Fig. 1c) provides a reference mark against which the actual distribution can be measured. This does not necessarily mean that a statistical distribution is best or even attainable for a given application.

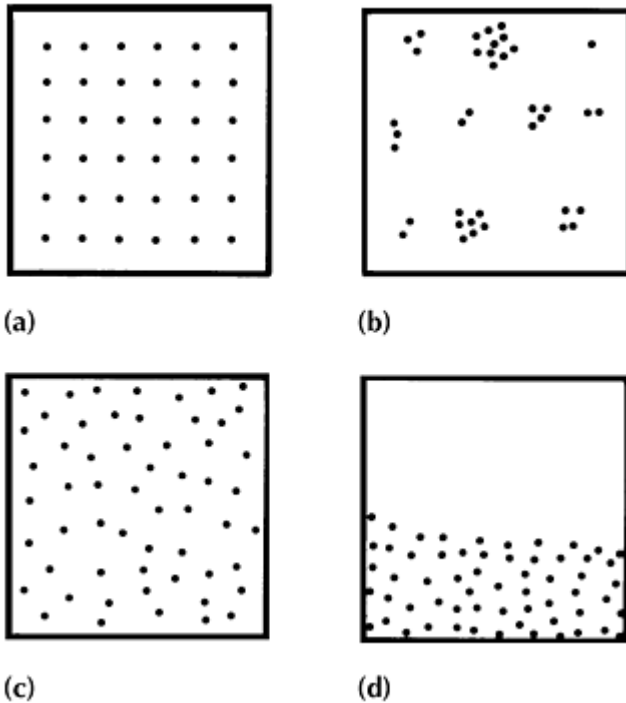

Fig. 1 Schematic representation of particle patterns in a powder mixture. (a) Ordered. (b) Agglomerated. (c) Statistical (random) distribution. (d) Demixed or segregated

The quality of a mixture can be described quantitatively by comparing the actual distribution of the components with that of a statistical mixture. An example of such a comparison, in terms of the number of contacts between identical particles in the binary iron-copper system, is shown in Fig. 2. In this sample the addition of a stabilizer minimizes segregation of components and helps produce a near-random (bottom curve) mixture.

Fig. 2 Effect of stabilizer on iron-iron contact formation in binary iron-copper system. Lower curve represents theoretical random mixture.

Statistical Analysis of the Blend. Analytical determination of the standard deviation of a mixture is described as a statistical measure of how much the concentration of one constituent in a sample varies from the true concentration that characterizes the entire blend. For ideal conditions, the standard deviation for a random mixture can be calculated if the mechanism of mixing is known. Thus, formulas for the calculation of standard deviation for the random mixture for certain cases of diffusional (Ref 1), convective (Ref 2), and shear mixing (Ref 3) exist. A statistical mixture of a typical two-component P/M premix depends on the component mass ratio, the average component masses, the standard deviations of the component particle mass distributions, and the sample size (Ref 4). Using statistics provides a structured method of analysis, but also has drawbacks. The standard deviation is related to the number of particles in the sample, and therefore the standard deviation is sensitive to particle size. Also, standard deviation is a raw statistical concept that does not directly indicate when a proper mix has been achieved. The experimenter must decide the acceptance criteria for the samples. Further details on statistical techniques are found in Ref 5 and 6.

The quality of a mixture can be assessed in terms of its uniformity, either on a macroscale or a microscale. The results of structure/property relationships, often of an empirical nature, usually determine which degree of uniformity must be attained in a given application. When evaluation of the blend or premix is desired, thief probes using spaced compartments are used to obtain multiple samples throughout the cross section of the batch, whether in a mixer, drum, or other storage container. The thief provides a reasonable look at sections within the mixing vessel, but there are some problems with its use. Inserting the probe through the surface of the powder will possibly force some surface material down with it. Secondly, when the sample compartments are opened, better flowing material can preferentially fill the sample port and bias the result.

Sample size should be related to the method of quality determination. Scale of scrutiny is a term used to define sampling criteria. If the mixed product is to be used in large quantities for a subsequent processing step, the scale of scrutiny can be a bag of the packaged product. If the mixed product is ultimately used for small parts, the scale of scrutiny can be a few grams. Ideally, the closer the sample size approaches the actual quantity used in analysis, the more accurate and consistent the results will be, because sample segregation will have minimal effect. Subdivisions of samples can yield nonrepresentative results, particularly when the materials are prone to segregate. To eliminate or reduce the effect of segregation related to particle size, reduction of large particle sizes by grinding or milling the sample is recommended. The number of samples taken should be determined by the application of the mix. Other factors such as analysis methods, analysis costs, and how the first few samples analyze to the expected assay ultimately dictate how many samples are required (Ref 7).

If the percentage of one component in a batch of blend or premix is X , and the percentage found in a spot sample is X_i , then the difference is $(X - X_i)$, which can be a plus or minus value. The average of all the X_i readings could approach the value of X if enough samples were checked; the average of all the plus or minus variations of $(X - X_i)$ would approach 0. To obtain a measure of the overall sample--the significance of all the spot samples--the statistical variance and standard deviation are computed. This involves averaging the squares of the individual sample errors, as illustrated in the simple example that follows. The following data represent analytical results of six spot samples (Ref 7) taken from a batch of mixed powder. The percentage of ingredient A in batch:

$$X = 40$$

Percentages measured in the spot samples:

$$X_1 = 41$$

$$X_2 = 45$$

$$X_3 = 38$$

$$X_4 = 42$$

$$X_5 = 36$$

$$X_6 = 38$$

To compute variance $(X - X_i)^2$.

$$\begin{array}{r} (40 - 41)^2 = 1 \\ (40 - 45)^2 = 25 \\ (40 - 38)^2 = 4 \\ (40 - 42)^2 = 4 \\ (40 - 36)^2 = 16 \\ (40 - 38)^2 = 4 \\ \hline 54 \end{array}$$

$$\frac{54}{6} = 9 \quad \sqrt{9} = 3$$

The number 9 is the biased variance, and 3% is the biased standard deviation. These values quantitatively characterize the batch of mixed powder. In mathematical form, it can be expressed:

$$S^2 = \frac{\sum_{i=1}^n (X - X_i)^2}{n}$$

where S^2 is biased sample variance, S is biased standard deviation, i is spot sample number, X_i is spot sample measurement, X is actual content of ingredient, and n is number of spot samples.

To compensate for the increased uncertainty entailed using very few spot samples, the unbiased variance is used. The difference is that $n - 1$ is placed in the denominator instead of n . The expression then becomes:

$$S^2 = \frac{\sum_{i=1}^n (X - X_i)^2}{n - 1}$$

The unbiased sample variance for the foregoing example is calculated to be:

$$s^2 = \frac{54}{6-1} = 10.8$$

$$s = \sqrt{10.8} = 3.3$$

Thus, 3.3% is the unbiased standard deviation. It is a statistical measure of the probable variation, plus or minus, from 40% of ingredient A in the blend, as measured by the sampling operation.

For more information on sampling, see the article "Sampling and Classification of Metal Powders" in this Volume.

Blending and Premixing of Metal Powders and Binders

Revised by Thomas Chirkot, Patterson-Kelley Co., Division of Harsco Corp.

Effect of Powder Characteristics

The present state-of-the-art blending and mixing does not permit a calculation or prediction of blending results based on available powder component data. Part of the reason for this is that some of the forces and phenomena operating during blending are not measurable and their relationships to blending are not known.

There is a general agreement in the literature (Ref 7, 8, 9) that the primary reason for segregation is the different flow rates caused by powder properties, or velocity gradients created by mixing, handling, transporting, or movement of materials. Segregation mechanisms that interfere with random motion of particles operate in combination, and reduction of industrial problems depends on minimizing the more severe ones (Ref 7). Some of the variables affecting flow, and thus segregation, are:

- Particle shape, size, and size distribution
- Surface roughness
- Surface hardness
- Particle density
- Material density
- Batch volume
- Ratio of components
- Electrostatic phenomena
- Mass flow conditions

Examination of the variables causing segregation indicates that segregation is a material, rather than a mechanical, problem. Campbell and Bauer (Ref 8) point out that segregation also occurs in processing equipment. Therefore, the cure lies in control, adjustment, or change of the variables affecting the powder or its mass behavior.

For fine powders, particularly those able to hold static charges, electrostatic charge phenomena often are at the core of the blending problem. In such cases, charge dissipators (such as water) and surfactants should be investigated first. The effects of particle size, shape, density, and surface characteristics (Ref 10) should then be evaluated if the problem persists.

Particle Size. As a general rule, the greater the uniformity of particle size of the material to be blended or components to be premixed, the greater the possibility for consistent and uniform results. As the particle size range and distribution change, a change in blendability should be expected. Larger particles of the same or of different materials have a strong tendency to segregate during blending or premixing. Elimination of the larger particle sizes, if feasible, is beneficial. Slowing down the blender, or the use of vacuum blending (wherein the atmosphere that supports and fluidizes the fines is absent), or mechanical or thermal agglomeration (as in the so-called diffusion-bonded grades of iron-base powders) also are possible solutions to segregation problems. Spray drying of multicomponent mixtures is another solution.

Particle Shape. The blendability of powder is strongly influenced by particle shape. Figure 3 shows the variability coefficient--that is, the standard deviation divided by the average value of the measured property--of 90%Fe-10%Cu mixtures for different particle sizes and shapes. For spherical iron, the quality of mixing improves quickly (lower coefficient of variability), but results in demixing as mixing is continued. Consequently, blending should be stopped once a random or near-random distribution has been achieved. Demixing or overblending is often caused by the accumulation of electrostatic charges, which often can be dissipated by the addition of a small amount of water. Surfactants can improve the flow of materials. This is illustrated in Fig. 4, which shows the beneficial effect of oleic acid for 90%Fe-10%Al mixtures.

Fig. 3 Effect of particle size and shape of components of 90%Fe-10%Cu mixtures on degree of blending. Quality of blending improves as variability coefficient decreases. Particle size and shape for components: a, Cu, 200 to 300 μm ; Fe, <63 μm of spherical particle shape; b, Cu, 200 to 315 μm ; Fe, 100 to 200 μm of spherical particle shape; c, Cu, 200 to 315 μm ; Fe <63 μm of irregular particle shape; d, Cu, 200 to 315 μm ; Fe, 100 to 200 μm of irregular particle shape

Fig. 4 Effect of stabilizer on degree of blending of 90%Fe-10%Al mixtures. Particle size for both components: 100 to 200 μm . Stabilizer: benzeneloleic acid. a, without stabilizer; b, with 1.0% stabilizer; c, 1.0% stabilizer added after 8 min of blending; d, 3% stabilizer added after 8 min of blending

The net effect of both particle size and shape on blendability tends to be the result of a combination of surface conditions (smooth, rough, or jagged) and the basic particle shape.

Density. One of the long-standing problems of blending and premixing has been density differences of the powders being processed. Low-density materials tend to "float" and collect at the top of a mass, while high-density components tend to "sink" to the bottom of the mix. The situation is aggravated if the heavy particles are coarse and the light particles are fines. Size and density differences can balance out, on the other hand, if the fines are denser than the coarse components. This is true of many water-atomized metal powders, in which the coarse fractions have more irregular particle shape, that is, their effective density is lower. For mixtures where small particles tend to coat the larger ones, a good blend usually depends on the uniform size of the small particles and a narrow ratio of the two components (Ref 7).

Hausner (Ref 11) has compiled some of the variables affecting loose powder density, as follows:

- Material density
- Particle shape
- Particle density (particle porosity)
- Average particle size
- Particle size distribution
- Average particle shape
- Particle shape distribution
- Specific surface area of the powder
- Oxide films
- Additions, such as lubricants
- Medium surrounding the particles

Hausner has shown the change in apparent and tap densities with differently shaped particles (Tables 1 and 2) and reported on tests made by Kothari (Ref 12) reflecting the apparent and tapped densities as affected by powder particle size (Tables 3 and 4). He has also described the importance of friction conditions in a mass of powders and the effects of particle size and shape on friction, as well as apparent and tap densities.

Table 1 Particle size distribution of the copper powders listed in Table 2

Mesh size	wt%
+100	1
-100 to +150	5
-150 to +200	35
-200 to +250	10
-250 to +325	30
-325	19

Table 2 Apparent and tap densities of three differently shaped copper powders of similar particle size distribution

Particle shape	Apparent density (d_a), g/cm ³	Tap density ^(a) (d_t), g/cm ³	d_t/d_a
Spherical	4.5	5.3	1.18
Irregular	2.3	3.1	1.35
Flake	0.4	0.7	1.74

(a) Vibrated in Synchron vibrator, at constant amplitude, for 10 min

Table 3 Apparent and tap densities of tungsten as affected by powder particle size

Particle size, μm	Specific surface, mm ² /g	Apparent density (d_a), g/cm ³	Tap density (d_t), g/cm ³	d_t/d_a
0.5	5480	2.58	4.32	1.68
3-4	1120	3.56	5.64	1.57
14-16	220	3.92	5.10	1.30

Table 4 Apparent and tap densities of three types of iron powders

Particle size, μm	Type of iron powder, wt%		
	Carbonyl	Electrolytic	Reduced
0-10	2.0	6.6	1.8
10-15	59.0	9.2	17.0
15-30	36.0	53.0	41.0
30-44	3.0	31.2	40.2
Apparent density, g/cm ³	3.42	2.56	1.89
Tap density, g/cm ³	4.09	3.42	2.12
d_t/d_a	1.20	1.34	1.12

Blending and Premixing of Metal Powders and Binders

Revised by Thomas Chirkot, Patterson-Kelley Co., Division of Harsco Corp.

Equipment for Blending and Premixing

Many different types of machines are available for blending and premixing solids. The high density, abrasive nature, frictional characteristics, and tendency to segregate of metal powders, however, reduce the suitability of some machines. A blender suitable for metal powders should:

- Achieve a maximum blending in minimum time
- Have a gentle mixing action to avoid particle degradation
- Provide repeatability of blending
- Provide for complete batch discharge
- Provide accessibility for ease of cleaning
- Have low power consumption
- Require low maintenance
- Provide dust-tight operation

The above list indicates that the use of high-shear paddle- or plough-type devices is inappropriate for metal powders, with few exceptions. Thus, the choice narrows down to tumble-type and low-shear agitated-type machines.

Tumble-type blenders meet the greatest number of the aforementioned criteria, making them the most desirable. Furthermore, scale-up from laboratory size tumblers is very precise. Drum-type, double cone, twin shell, and cross-flow, as well as other tumbler shapes, all produce some quality or degree of blending and also permit straightforward scale-up. Some of these have obvious shortcomings, such as lack of material movement along the axis of rotation, incomplete discharging, and lack of accessibility to the internal surfaces for cleaning. Figures 5 and 6 illustrate the effects of the ratio of total powder volume to mixer volume and the effect of baffle plates in cylindrical mixers on mixing quality.

Fig. 5 Effect of powder fill in mixer on quality of mixing

Fig. 6 Effect of baffles on quality of mixing in cylindrical mixer. Radius of cylindrical mixer: R , rotational speed: 25 rpm. a, no baffle plates; b, height of baffle plate: $0.66 R$; c, height of baffle plates: $0.5 R$; d, height of baffle plates: $0.33R$

Low-shear agitated-type blenders, using ribbons, slow-speed paddles, screw-type augers, and other means of moving components in a stationary vessel, are inferior to tumblers. Excessive power consumption resulting from driving the submerged mixing device through the mass of dense metal powders, grinding action caused by the relative motion between the moving and stationary parts, excessive wear of the agitator in an abrasive medium, and lack of precision mixing capability are the main drawbacks. Also, ribbon blender effectiveness does not scale up in direct proportion to laboratory models.

The ideal mixer has not yet been invented. Material variables have such an overwhelming influence on the results obtained from any mixing operation that it is mandatory to sample and analyze to arrive at the best combination of materials and equipment for each application.

Effect of Blending Techniques on Properties of Metal Powder Mixes

François Chagnon, Quebec Metal Powders Limited

Introduction

THE PRODUCTION OF P/M PARTS generally requires admixing of various constituents into metal powders in order to promote part compaction and ejection from the die and obtain adequate strength through diffusion of these elements during the sintering process. Solid lubricants are generally used in a range of 0.5 to 1.5%, depending on the part density and size, to allow part ejection and maintain good surface finish. In the case of iron and steel powders, constituents such as graphite, copper, nickel, or ferroalloys are used to increase strength through diffusion during the sintering process. Finally, other elements such as manganese sulfide or boron nitride may also be admixed to improve machinability of P/M parts. These elements must be uniformly mixed to ensure part-to-part consistency during the compaction and sintering operations. Also, because of differences in particle shape, size, and density of these various powders and low specific gravity, fine particles are susceptible to demixing and dusting, which are a major cause of variations in chemical composition of mixes and hence of the dimensional change and mechanical properties of P/M parts.

Two blending techniques are generally used in the P/M industry to prepare press-ready mixes. The first technique consists of dry mixing the various constituents to get a homogeneous mixture. The second technique, binder treatment blending, makes use of binding agents to reduce segregation and dusting during powder handling.

Dry Mixing of Metal Powders

Dry mixing is the most common way to produce press-ready mixes. Metal powders and additives are charged into a blender, mixed until a homogeneous mixture is achieved, and discharged into containers. Adding elemental constituents to metal powders can affect the physical properties of the mix such as flow rate and apparent density. If the additives are very fine, they have a tendency to segregate and create dust during handling. It is a common practice in the P/M industry to adjust the physical properties of a mix by proper use of additives, particularly the lubricant. Figures 1 and 2 illustrate how the type of lubricant can affect apparent density and flow rate, respectively, of iron powder mixes. Stearate-base lubricants generally increase apparent density and improve flow rate of iron powder mixes. Mixes containing ethylene bis-stearamide (EBS) wax exhibit lower apparent density and slower flow rates than mixes containing stearates. Polyethylene wax significantly lowers the apparent density and adversely affects the flow rate of iron mixes

Fig. 1 Effect of lubricant types on apparent density of iron powders mixes (FC0205 mixes with 0.75% lubricant)

Fig. 2 Effect of lubricant types on flow rate of iron powder mixes (FC0205 mixes with 0.75% lubricant)

Admixed elements, particularly the lubricant, can also affect the green properties, compressibility, and green strength of the P/M parts as illustrated in Fig. 3 and 4. Powdered EBS and polyethylene waxes in iron powder mixes reduce compressibility and improve green strength. Stearate lubricants have good lubricating properties and maintain good mix compressibility, but lower the green strength.

Fig. 3 Effect of lubricant types on compacting pressure of FC0205 specimens (mixes containing 0.75% lubricant)

Fig. 4 Effect of lubricant types on green strength of FC0205 specimens (mixes containing 0.75% lubricant)

Effect of Blending Techniques on Properties of Metal Powder Mixes

François Chagnon, Quebec Metal Powders Limited

Binder Treatment of Metal Powder Mixes

This technique consists of binding the fine additives to the coarser ones by adding a small quantity of binding agent to the powder. This binder creates a thin film that covers the particles causing the fine additives to adhere to the base powder. Binders can be of two types: liquid or solid (Ref 1). In the case of liquid binder (Fig. 5a), a dry mix is produced and the liquid binder is subsequently added to the mixture. Further homogenization is required to ensure that the liquid is evenly dispersed throughout the mix. This operation can be done in conventional blender units commonly used in the P/M industry. Kerosene is a well-known liquid binder, but tall oil (Ref 2), types of glycol, glycerin, and polyvinyl alcohol (Ref 3) may also be used to prevent segregation.

Fig. 5 Processing techniques of binder-treated mixes (Ref 1)

As shown in Fig. 5(b), solid binders must be dissolved in an appropriate volatile solvent that acts as a carrier. The solution is then sprayed onto the mix. After homogenization, the solvent is extracted and the binder itself remains as a thin coating with the fine additives on the surface of powder particles. The solvent can be recovered in a condensation chamber and recycled. For iron powder mixes, many types of polymeric binders have been evaluated and proven their efficiency (Ref 4, 5, 6, 7, and 8). Another derivative of liquid binder is described in Ref 9. Oleic acid is sprayed onto an iron-powder-base mix containing zinc stearate, graphite, and other additives. The blender is then heated above the melting point of the lubricant, 110 to 130 °C, and the liquid lubricant acts as a binder. The mixture is then cooled to room temperature and packaged.

Effect of Blending Techniques on the Physical and Green Properties of Metal Powder Mixes Dust Resistance. One attribute of binder-treated mixes is a better resistance to segregation and dusting. A test method to evaluate the efficiency of the binder agent is described in Ref 8. This is a measure of the resistance of the powder mix to dusting when fluidized by a stream of gas, generally air or nitrogen. Figure 6 illustrates a schematic of the apparatus used in this test method. An air stream is injected at a constant flow rate of 6.0 L/min for 10 min through a 2.5 cm diam tube with a 400 mesh screen upon which the mix sample is placed. This causes the mix to bubble and the fine particles, such as graphite, to be entrained as a result of a large surface to volume ratio and low specific gravity. The graphite and other similar materials are then deposited in the dust collector. The dust resistance factor is the ratio of the chemical content of the element before and after the test.

Fig. 6 Dust-resistance apparatus

Figure 7 illustrates the effect of binder concentration, solid or liquid, on the graphite and lubricant dust resistance of a F0008 mix containing 0.8% zinc stearate. Without the addition of a binder, the typical dust resistance of the mix is 45%. This means that only 45% of the graphite and the lubricant was retained in the test sample. The various binders improve the dust resistance up to a concentration of 0.10%. The kerosene has the lowest dust resistance factor, 70% for a 0.10% addition. Glycol, which is also a liquid binder, shows better results: 90% for an addition of 0.10%. A solid binder, such as polyvinyl pyrrolidone (PVD), shows the best results. Dust resistance of about 95% is reached for a 0.10% binder addition.

Fig. 7 Effect of binder concentration on carbon dust resistance of iron powder mixes (F0008 with 0.80% lubricant) (Ref 1)

Flow rate is an important parameter in the production of metal powder mixes because it directly affects the quality and the productivity of compacting presses. As shown in Fig. 8, liquid binders deteriorate mix flow rate, potentially limiting their use. However, the use of a solid binder significantly improves the flow rate of powder mixes. This is an important attribute because it directly impacts on the productivity and the quality of the parts (Ref 10). A better flow rate results in increased press productivity because the die cavity can be filled faster than with a regular mix. Also, because of the superior flow characteristics, complex and thin-walled parts can be produced with better control of weight and density. An example of how the quality and productivity are enhanced by the use of binder-treated mixes is illustrated in Fig. 9. In this example, an index of 100% was assigned to the standard condition. The part weight (C_p) index in this condition was 1.3 for the regular mix and 2.4 for the binder-treated mix. The C_p index is a direct measurement of the scatter, which indicates that the binder-treated mix achieved a reduction of nearly 55% in weight variation. Another interesting point is that even with an increase in press productivity to 113%, the C_p index is nevertheless 25% higher than the regular mix processed at a lower production rate.

Fig. 8 Effect of binder concentration on flow rate of iron powder mixes (F0008 with 0.80% lubricant) (Ref 1)

Fig. 9 Comparison of regular (reg) and binder-treated mixes (BTM) processed on a production press (FC0208 modified)

Green properties --mix compressibility and green strength--are also critical parameters in the production of P/M parts and can be affected by the blending technique. The film rigidity of the binder can be controlled by using a plasticizer (Ref 11), which significantly improves the green strength of P/M parts (Fig. 10) and maintains good mix compressibility. For multilevel parts, the powder mix must adequately fill the die cavity with a constant quantity of powder for each press

stroke. If the different sections of the die cavity are not well filled, the powder transfer during the compacting cycle can create density gradients and negatively affect the green strength. As shown in Fig. 11, laboratory results show a 25% green strength improvement, while for production parts the improvement is nearly 45%. This is caused by a lower density gradient throughout the different sections of the part.

Fig. 10 Effect of binder treatment on green properties of laboratory specimens (FC0205 modified mixes)

Fig. 11 Effect of binder treatment on relative green strength of laboratory specimens and production parts (FC0205 modified mixes)

Binder-Treated Mixes for High-Density Parts. Recent innovations (Ref 12, 13, 14, 15, 16, 17, 18, and 19) have adapted the binder-treatment technology to successfully heat and press metal powder mixes at temperatures up to 150 °C. This compaction technique can increase green densities by about 0.1 to 0.2 g/cm³ as compared with parts compacted at room temperature. However, these mixes must show good physical characteristics, particularly flow rate and apparent density, over a wide range of temperatures. To withstand these temperatures, powder mixes are produced with a high-melting-point lubricant and binder treated to improve flow rate and stabilize apparent density. As shown in Fig. 12, binder-treated mixes must be used for these specific temperature conditions because they show consistent apparent density at the working temperature. As previously mentioned, stable apparent density and good flow rate are key

parameters to achieve constant die filling from stroke to stroke and hence minimize press adjustment and maintain good part-to-part consistency.

Production of Iron Powder*

Introduction

IRON POWDER represents the largest tonnage of raw materials used in P/M fabricating. Iron powder leads in commercial P/M applications because (1) it is inexpensive to produce compared to nonferrous metals; (2) it possesses superior properties, particularly strength, compared to other metals or nonmetals; (3) it has a favorable strength-to-weight-to-cost ratio; (4) it alloys readily, especially with carbon, and consequently possesses all of the attributes of the iron-carbon system (including heat treatability); and (5) it is available in sufficient quantity. Iron powder is not limited to the manufacture of P/M parts. About one-third of all iron powder produced is used for applications such as welding rods, flame cutting, food enrichment, and electronic, magnetic, and chemical applications.

Production of iron powder by the reduction of iron oxide, and in particular the reduction of iron ore by carbon, is the oldest method of producing iron powder. The Swedish sponge iron process, which was developed in Höganäs, Sweden in the early 1900s, was originally intended to produce metallic iron in sponge form as the raw material for steelmaking. A modified version of the process is still one of the important industrial methods of producing iron powder and is practiced in Sweden and in the United States. A similar adaptation also is used in the Soviet Union.

The Swedish sponge iron process is one of many developed for the direct reduction of iron ore to metallic iron at temperatures below the melting point of iron. However, metallic irons produced by most of these direct reduction processes are not suitable for use as iron powder in the production of P/M iron and steel products because they contain too high a percentage of impurities. Also, they do not have the required physical and mechanical properties, such as particle size and distribution, particle shape, low internal particle porosity, and lack of strain hardening.

Most powders currently used for P/M stainless steels, low-alloy steels, and tool steels are produced by atomization of the molten alloy (where melting points of these alloys are lower than that of pure iron). Water-atomized steel powders became available in the early 1960s as a direct result of the invention and commercialization of water-atomized iron powders made from low-carbon iron. Atomized iron and steel powders require the same type of melting and atomizing facilities and methods, but this article only discusses iron powder production by water atomization. Production of alloy steel powders is described in the article "Production of Steel Powders" in this Volume.

A significant portion of low-carbon irons for powder metallurgy are produced by water atomization. Nonetheless, this article also focuses on production of iron powder by reduction and other chemical processes below the melting point of iron. The methods discussed in this article are:

- The Höganäs process
- The Pyron process
- Carbonyl vapor metallurgy
- Electrolytic iron
- Fluidized-bed reduction
- Water-atomized iron powders

The focus is on iron powder production, although some of these processes are also adapted to produce alloy powders.

The Höganäs Process

The Höganäs process uses pure magnetite (Fe_3O_4) ore found in northern Sweden, which has an iron content of approximately 71.5% after beneficiation by grinding and magnetic separation. The impurities present in small amounts are not in solid solution in the oxide, but exist as discrete phases. The ore is of consistent quality and is available in sufficient quantities for continued usage.

Coke breeze or another carbon source that provides the reducing agent is required to produce sponge iron powder. Additionally, limestone is used to react with the sulfur contained in the coke and to prevent its inclusion in the iron powder as an impurity. The ore is prepared for reduction and drying in a rotary kiln, followed by magnetic separation. Coke and limestone are mixed in the proportion of 85% coke and 15% limestone. This mixture also is dried in a rotary kiln and then crushed to uniform size.

The ore and the coke-limestone mixture are then charged into ceramic tubes, which consist of silicon carbide. A pair of concentric steel charging tubes is lowered to the bottom of the ceramic tubes. The ore is fed between the steel tubes. The coke-limestone mixture is fed within the inner of the two concentric charging tubes and between the outer charging tube and the inner wall of the ceramic tube. The charging tubes are then withdrawn from the ceramic tube, leaving the ore and the reduction mixture in contact with one another, but not intermixed.

Charged ceramic tubes are placed on kiln cars that carry them into the kiln. Ceramic tubes are arranged in rows of six tubes by six tubes per kiln car. Cars are pushed into a long tunnel kiln where the reduction occurs. Every 53 min, one car is pushed into one end of the kiln, while another car is removed at the other end. The total time that a car is in the kiln is about 68 h. Gas burners heat 150 m (500 ft) of the tunnel to a temperature of 1260 °C (2300 °F); the remaining 19 m (62 ft) are cooled with circulating air. The tops of the kiln cars form the bottom of the heating chamber.

Within the hot zone of the tunnel kiln, several chemical reactions occur. Decomposition of the limestone generates carbon dioxide, which oxidizes the carbon in the coke to form carbon monoxide. Carbon monoxide reacts with magnetite to form additional carbon dioxide and ferrous oxide. The ferrous iron oxide is further reduced by the carbon monoxide to metallic iron. Metallic iron particles are sintered together to form sponge iron cake. Additionally, a reaction occurs between the sulfur contained in the coke and the limestone admixed to the coke.

The thermodynamics and the kinetics of the process by which iron oxide is reduced to metallic iron have been studied repeatedly, but it is difficult to apply the results of these studies to the conditions found in the Höganäs sponge iron process. When the material in the ceramic tubes has been cooled to room temperature at the end of the reduction process, 96% of the oxide has been reduced to iron. The iron contains 0.3% C. The reduced iron particles sinter together to form a hollow cylinder of sponge iron that has pores between and within the iron particles.

Figure 1 shows the cross section of +40 mesh ground magnetite powder. Figure 2 is a micrograph of the cross section of +40 mesh sponge iron powder obtained by reduction of the magnetite at 1250 °C (2280 °F). While the magnetite particles are dense, those of the reduced iron powder are highly porous. Figure 3 illustrates sponge iron particles etched with 2% nital after polishing. Residual unreduced oxide is evident in Fig. 3. Also, etching highlights the very small grain size of the iron produced by reduction of the oxide.

Fig. 1 Cross section of +40 mesh ground magnetite. 30×

Fig. 2 Cross section of +40 mesh sponge iron obtained by reduction of ground magnetite. 125×

Fig. 3 Cross section of sponge iron particles. Etched with 2% nital. 180×

After removal from the kiln, cars are transferred to the discharge section. Cylindrical cakes of sponge iron are removed from the ceramic tubes and dropped into a tooth crusher, where they are broken into pieces approximately 25 mm (1 in.) in diameter. The emptied ceramic tubes are cleaned and transferred to the charging station, where they are reloaded for successive reduction runs.

The 25 mm (1 in.) diam sponge iron lumps undergo a series of grinding, magnetic separation, and screening steps to produce a powder of the desired particle size distribution and to remove nonmagnetic impurities, while preserving the porous nature of the powder particles that makes them well suited for P/M fabrication. Consequently, grinding is continued only until about 65% of the powder passes through a 100 mesh screen. For P/M purposes, however, a -100 mesh powder is generally required. Oversize powder is separated by screening and is used for coating welding electrodes and other non-P/M applications.

Only minor changes in chemical composition of the powder occur during grinding, magnetic separation, and screening. The resultant powder contains approximately 1% O and 0.3% C. However, the powder has been strain hardened considerably. Consequently, it is annealed in a belt furnace.

Powder is loaded onto a solid stainless steel belt that carries it into the furnace through a powder-lock arrangement. This mechanism seals the entrance of the furnace and prevents air from entering. The powder is heated to about 870 °C (1600 °F) in an atmosphere of dissociated ammonia. During annealing, the carbon in the powder is essentially removed, and the oxygen content is reduced from 1% to about 0.30%. At the same time, strain hardening introduced during grinding is relieved. During annealing, the powder is loosely sintered, but requires only light grinding and screening to produce a finished product ready for packing and shipping to P/M fabricators.

Reduction and annealing steps in the production of sponge iron are essentially continuous, but there are several holding areas between operations. These holding areas assist in producing a powder of uniform quality through an "equalizing" process, which consists of recirculating the powder by withdrawing it from the bottom of the containers in the holding areas and feeding it back at the top.

Figure 4 is a scanning electron micrograph of Hoeganaes Ancor MH-100 iron powder particles. Irregular shape of the particle surfaces and particle porosity are visible. Typical powder properties are:

Production of Iron Powder*

The Pyron Process

Revised by Stephen Claeys, Pryon Inc.

The Pyron process provides an alternative for the production of iron powders by the reduction of oxides. Instead of using ground iron ore as the raw material for reduced iron powders, the Pyron process uses mill scale taken from steel mills that produce plain carbon steel products, such as sheet, rod, wire, plate, and pipe. Mill scales containing alloying elements other than manganese are not used. A flowchart of the Pyron process is shown in Fig. 5.

Fig. 5 Flowchart of Pyron iron powder process

Process Conditions. Mill scales from different mills are mixed by layering in a bed that is large enough to supply the plant with a constant feed for up to 3 months. Scale is scalped as it is fed to the plant to remove large, undesirable objects. It is then magnetically cleaned to remove any sand, dirt, or other nonmagnetic material. The mill scale is then ground in a continuous ball milling operation to -100 mesh. Careful control of this operation ensures desired particle size distribution.

Oxidation at about 980 °C (1800 °F) converts the iron oxides that are present in the mill scale, FeO and Fe₃O₄, to ferric oxide (Fe₂O₃). This operation is critical to the Pyron process and is necessary to ensure the uniform properties of Pyron iron powders. Gas-fired, fluidized-bed roasters are used for this operation.

Hydrogen reduction is done in electric furnaces 37 m (120 ft) long. The prepared oxide is carried from the roasters through the reduction furnace on 183 cm (72 in.) wide belts. It is converted to iron:

Hydrogen in this reaction is supplied by pipeline from a nearby chemical manufacturer. It circulates through the furnace in a totally enclosed system that removes water and returns the unspent hydrogen to the furnace.

Reduction is done at about 980 °C (1800 °F). Small adjustments in temperature and belt speed are needed to control quality. The resulting sinter cake is friable, and a simple milling operation converts it to iron powder. Particle size distribution is determined by the original grinding of the mill scale. From the milling operation, the powder is conveyed to large storage bins, where it is subsequently scalped and blended.

Pyron iron powder has fine porosity and a sponge-like microstructure (Fig. 6 and 7). The pores in the interior structure of Pyron iron powder particles (Fig. 7) are considerably finer than those in Swedish sponge iron powder particles, because in the latter the long-term reducing treatment at higher temperature coarsens the pores. Because of the fine pore structure, compacts from Pyron iron powder sinter faster than those from other commercial iron powders. Properties of several grades of Pyron iron powder are given in Table 1. Table 2 lists characteristics and uses of hydrogen-reduced iron powders produced by the Pyron process. Typical chemical compositions (wt%) of Pyron powders are:

Total iron, wt%	97.0-98.5
Carbon, wt%	0.01-0.05
Sulfur, wt%	0.005
Phosphorus, wt%	0.012
Manganese, wt%	0.40-0.65
Acid insolubles:	
AC-325	0.20-0.90
Other grades	0.20-0.45
Oxygen (typical), wt%	0.70-1.75

Carbonyl Iron Powders

Revised by Sotiri Papoulias, International Specialty Products

Very fine iron powders, like nickel powders, can be produced by carbonyl decomposition (vapor metallurgy) techniques. The first patents covering the carbonyl process were registered to Ludwig Mond in 1890. A brief review of early metal carbonyl research, with emphasis on his work, is presented in the article "Production of Nickel-Base Powders" in this Volume. In addition, some of the different types of metal carbonyls that can be formed and the formation and decomposition reactions of carbonyls used for the production of primary metal and powder products are described in that article in the discussion of nickel carbonyl powders. This section, however, deals only with the production of iron powders produced by the decomposition of iron pentacarbonyl, $\text{Fe}(\text{CO})_5$.

Process Conditions. Iron pentacarbonyl, the raw material from which carbonyl iron powder is produced, is a liquid with a boiling point of 102.8 °C (217 °F). It is formed by passing carbon monoxide over a reduced sponge iron at relatively high pressures and at temperatures ranging from 170 to 200 °C (340 to 390 °F). The physical properties of iron pentacarbonyl are:

Formula	$\text{Fe}(\text{CO})_5$
Color and state (room temperature)	Viscous yellow liquid
Molecular weight	195.9
Iron, %	28.51%
Melting point, °C (°F)	-21 (-5.8)
Boiling point, °C (°F)	102.8 (217)
Specific gravity (room temperature)	1.457
Heat of formation, kJ/g · mol (kcal/g · mol)	-964.0 (-230.2)

Typically, the feed stocks used are high-surface-area oxidized iron powders or iron turnings that are reduced in hydrogen or another suitable atmosphere prior to carbonylation. The presence of oxygen or oxides on the surface of the iron hinders the reaction, whereas the presence of catalysts improves the rate of formation.

The reaction is exothermic. To achieve commercial production rates, carbonylation is conducted at 130 to 180 atm (1900 to 2600 psi) and temperatures of 170 to 175 °C (340 to 350 °F). As shown in Fig. 8, iron pentacarbonyl formation increases with increasing carbon monoxide pressure. Increasing the temperature increases the rate of reaction. Increasing pressure prevents excessive decomposition of the carbonyl. At temperatures above 200 °C (390 °F), carbonyl yield is reduced rapidly by the increased conversion of carbon monoxide to carbon and carbon dioxide by the disproportionation reaction. Iron pentacarbonyl is then condensed and purified by distillation, whereupon it reverts to di-iron nonacarbonyl, $\text{Fe}_2(\text{CO})_9$.

Fig. 8 Effect of system pressure of 100 to 300 atm (1470 to 4400 psi) and temperature on the formation of iron pentacarbonyl. Source: *J. Chem. Soc.*, Vol 121, 1922, p 29-32

The rate of decomposition for di-iron nonacarbonyl is temperature dependent, with maximum rates achieved at about 200 to 250 °C (390 to 480 °F). At higher temperatures, the iron produced oxidizes in the carbon monoxide atmosphere, and high-carbon powder is formed.

Present Commercial Processes. In the United States, International Specialty Products (formerly GAF Corporation) currently produces high-purity iron powder using carbonyl decomposition technology. In Europe, BASF produces carbonyl iron powders using the same decomposition product, but employing scrap iron as source material. The GAF (ISP) process starts with high-purity iron. Iron powder, or sponge, which is initially treated under hydrogen to reduce surface oxides to metallic iron. This feedstock is then reacted with carbon monoxide under pressure at elevated temperature to form liquid iron pentacarbonyl. Subsequently, the carbonyl is vaporized and thermally decomposed to form "crude" carbonyl iron powder. The crude powder is refined chemical processing and mechanically separated to yield various size grades of powder. The carbon content of the powder may reach a maximum of 0.8%, which is reduced to as low as 0.075% to satisfy specific requirements.

Powder Properties. High-purity iron powders produced using carbonyl technology are typically spherical and are available in several grades that range from 2 to 9 μm Fisher subsieve size, with apparent densities of 1.2 to 3.2 g/cm³. The powder can be produced at or near atmospheric pressure. Particles characteristically exhibit an onionskin structure due to minute carbon deposits in alternate layers. The high purity of these powders makes them an excellent starting material for the production of magnetic cores and electronic components. This powder oxidizes readily in air and is packaged under an inert gas to facilitate storage.

These powders are essentially free of nonferrous metals and contain 0.3% O, 0.075 to 0.8% C (depending on the grade), and 0.05 to 0.9% N. Alloy powders also are available that nominally contain 92.5% Fe (minimum), 0.8% C, 0.3% O, and 6.0% N. Primary applications of these powders include:

- High-frequency cores for radio transmitters, telephones, televisions, direction finders, VHF and UHF circuitry, and radar equipment
- Magnetic-fluid clutch and brake systems
- Carbide and diamond cutting tools
- Chemicals
- Pharmaceuticals (iron supplements, multivitamins)
- Catalysts
- P/M materials and alloys
- Cermets
- Magnetic coatings and tapes

- Radar-absorbing materials
- Food enrichment and animal feed

More information on applications is given in the article "Specialty Applications of Metal Powders" in this Volume.

Production of Iron Powder*

Electrolytic Iron Powder

Revised by Prasan Samal, OMG Americas

Iron powder made using electrolytic deposition has the highest level of purity among all types of commercially available iron powders. It possesses very irregular particle shape and consequently offers relatively large surface areas per unit mass (typically 0.1 to 1.0 m²/g). As a result of its high purity and irregular particle shape, it exhibits excellent compressibility and green strength. Its high level of purity and large surface area also render it desirable for many chemical, catalyst, and food-additive applications. Despite these unique attributes, the usage of electrolytic iron powder is limited due to its high cost of manufacture. Before improvements in the atomization of molten metal permitted the production of iron powders with relatively low oxygen contents and with moderate levels of purity, electrolytic iron powder was used widely for the manufacture of conventional P/M parts.

For many years, the telephone industry used electrolytic iron powder for manufacture of magnetic cores. Magnetic core and P/M magnet applications make up a sizable portion of the total volume of usage of electrolytic powder currently. Other applications include dry toner carrier for plain-paper photocopiers, iron-enrichment additives in foods, exothermic food heaters and hand warmers, catalysts, and chemical reagents. Of all other commercially available iron powders, only the carbonyl iron powders offer similarly high level of purity. However, carbonyl iron powders contain larger amounts of carbon and nitrogen, and are somewhat higher in cost.

Process Conditions. Manufacture of a metal powder by the electrolytic process can be achieved by one of two methods: a loosely adhering, powdery deposit may be formed directly on a permanent cathode, or a smooth, dense layer of refined metal may be deposited on a cathode and subsequently milled to obtain powder. Electrochemical polarization characteristics of the metal being processed largely determine which process can be used. In metals with low electrochemical polarization properties, such as copper, silver, zinc, and cadmium, the deposition potential varies little with current density; thus, spongy or powdery deposits, which can be scraped off as a powder, can be formed easily on the cathode. In metals with high electrochemical polarization properties, such as iron, nickel, and cobalt, a large change in the cathode potential is required to cause a relatively small change in current density. Consequently, smooth, coherent deposits are obtained with these metals. Electrolytic iron is, therefore, deposited on the cathode as a dense, brittle, and relatively thick layer, which is pulverized for the manufacture of the powder.

Two types of electrolytes are commonly used for the electrodeposition of iron: chloride and sulfate baths. Each has certain limitations and advantages over the other. Chloride baths can have higher concentrations of iron ions due to the greater solubility of ferrous chloride in water. High ionic concentration of the bath increases its conductivity, thus lowering power consumption. Chloride baths are, however, more corrosive than sulfate baths. The iron powder and chips produced in chloride baths contain small amounts of chlorides (about 0.10%), which are usually more objectionable than the residual sulfur found in products of sulfate baths.

Commercial Processes. Currently, OMG Americas (formerly SCM Metal Products) is the sole producer of electrolytic iron powder in the United States. The production process is based on a sulfate electrolyte with soluble anodes.

The electrolytic cells measure about 3 m (10 ft) long by 0.75 m (2.5 ft) wide by 0.75 m (2.5 ft) deep. The electrolyte consists of a mixture of ferrous and ammonium sulfates. Each cell contains 17 consumable anodes interspersed with 16 reusable cathodes. The iron from the anodes is deposited on the cathodes.

Electrodeposited iron is stripped off the cathodes periodically, and the deposits are broken into chips, approximately 15 mm ($\frac{5}{8}$ in.) \times 15 mm ($\frac{5}{8}$ in.) in size. Chips are ground in closed-type continuous ball mills or batch-type mills as

determined by the fineness of powder required. Mills are purged with an inert atmosphere, such as nitrogen, to prevent excessive oxidation. Milled powder is classified using various types of screens and classifiers. Although some powder is used in the as-milled condition for applications such as food enrichment and chemical reagents, other applications require that the powder be annealed. Annealing softens the powder, increasing its compressibility, and modifies its magnetic characteristics. Annealing is usually carried out in hydrogen-containing atmospheres, which also reduces the oxygen content of the powder.

Blending to ensure uniformity is the final step in processing. Samples are taken from the blended powder for conducting various quality control tests, including chemical analyses and physical properties.

Powder Properties. Table 3 compares the properties of a compacting grade of electrolytic iron powder (annealed) with those of typical atomized and reduced-iron powders. Figure 9 graphically depicts the compacting properties of this powder.

Table 3 Chemical and physical properties of compacting-grade iron powder

Fig. 9 Compacting properties of electrolytic OMG A-210 iron powder. Powder admixed with 0.5% zinc stearate for lubrication

The high compressibility and green strength of this powder make it very suitable for manufacture of intricate and fragile parts. Also, as a result of its intrinsic low hardness and freedom from refractory and oxide contaminants, it does not cause excessive die wear. Electrolytic iron powder also offers superior sintered properties, such as ductility and dimensional accuracy, achievable with reasonable compacting pressures. Figure 10 shows the relationship of sintered properties to green density. Table 4 lists the properties of various grades of electrolytic iron powders.

Fig. 10 Mechanical properties of pressed and sintered electrolytic iron powder compacts. Note: OMG A-210 powder was mixed with 0.5% zinc stearate, pressed into standard MIPF test bars, and sintered in dissociated ammonia atmosphere at 1120 °C (2050 °F) for 30 min.

Applications. The high green strength, high compressibility, irregular particle shape, and high purity of electrolytic iron powder make it suitable for a number of P/M applications. It is ideal for high-density, close-tolerance applications. Secondary operations are readily performed on high-density components made from electrolytic iron powder. Because of the irregular particle shape, re-pressed parts made from electrolytic iron powder have interconnected porosity eliminated at a lower density level than with more regularly shaped atomized iron powders. Hence, the risks of entrapment of plating solutions or infiltration of brazing filler material are minimized.

In applications requiring case-hardening heat treatment, electrolytic iron powder offers a very uniform case depth due to high density and freedom from interconnected porosity. For optimal control of case hardening, a minimum density of 7.2 g/cm³ is recommended. In full-dense applications, the low oxide inclusion content (acid insolubles) of electrolytic iron powder accounts for the superior dynamic properties of the parts, such as fatigue and impact strengths. The superior green strength of electrolytic iron powder also makes it ideal for use as the matrices for abrasive cutting wheels and diamond-bonded saw segments.

Annealed electrolytic iron powder is used in the manufacture of ferromagnetic cores for radios, televisions, and other audio devices. The common designs of ferromagnetic cores made from these powders are the E-type, C-type, and toroids.

Electrolytic iron powder is also used for making soft magnetic parts because of its high compressibility and freedom from impurities. For maximum magnetic properties, soft magnetic parts should be pressed to the highest practical density from a powder mix that contains a minimum amount of lubricant. To minimize carbon contamination, sintering is best carried out in dissociated ammonia, vacuum, or hydrogen. Other magnetic applications include magnetic strip produced by direct powder rolling and additives for Nd-Fe-B magnets.

Annealed electrolytic iron powder, screened to closely controlled particle size range, is used as a developer or carrier in toners for plain-paper copier machines. The irregular particle shape and magnetic quality of high-purity iron powder result in a magnetic brush of high loading characteristics that allows the toner to be uniformly transferred to the paper, thus providing high-contrast copies.

Unannealed, ultrafine (average particle size of about 10 μm) electrolytic iron powder is used for enrichment of food products. This grade of electrolytic iron powder meets or exceeds all specifications of the *Food Chemical Codex*. In addition to possessing the high purity required for this application, these powders exceed other iron powders, such as carbonyl and reduced-iron powders, in bioavailability because of their large specific surface area.

Other food-related applications include uses as desiccants for packaged food, to getter oxygen; and as self-contained food warmers especially for military and camping food packages. Similar disposable heating devices made using electrolytic iron are also sold as hand warmers for camping and other outdoor activities. Some electrolytic iron powder is used in the oxygen candles by the mining industry.

The high purity and large specific surface area of electrolytic iron powder make it an excellent candidate for many chemical reagent and catalyst applications.

Production of Iron Powder*

Fluidized-Bed Reduction

Fluidized-bed processes currently are used extensively in industrial applications. Process variations include fluidized-bed combustion, gasification, heat treatment, and catalytic reactions. Attractive characteristics of fluidized-bed processes include high, uniform heat transfer between gas and solid and high reaction rates due to the large exposed surface area of the fluidized-bed solid material. Fluidized-bed oxidation of metals and reduction of metal oxides are possible, but defluidization caused by sticking, as well as the pyrophoricity of reduced powders, has restricted industrial usage.

This article describes the processes of fluidized-bed reduction of iron oxides that were used from 1958 to 1970. Oxide reduction, atomization, electrolytic deposition, and carbonyl processes have replaced the fluidized-bed process for current iron powder production.

Typically, in the fluidized-bed process a granular material is kept in fluid motion by using a fluidizing gas. In many cases, the fluidizing gas reacts chemically with the granular solid. Thus, in fluidized-bed oxidation, the fluidizing gas typically is air or oxygen. In fluidized-bed reduction, the fluidizing gas contains hydrogen or carbon monoxide, or a mixture of the two.

Principles of Fluidized Reduction Processes. Many of the principles of fluidized-bed reduction were developed as a by-product of research aimed at direct ironmaking, that is, bypassing the reduction of iron ores in a blast furnace and replacing this procedure with continuous fluidized-bed reduction of iron ore. Iron processed in this manner is referred to as direct-reduced iron. To a great extent, these principles also apply to the reduction of high-purity iron ore or iron oxide, where the reduced iron is used in metallurgical applications without further processing.

For direct-reduced iron production, ore feed in the form of pellets is preferred (Ref 2). Fully oxidized pellets, such as hematite (Fe_2O_3) pellets, should be used, because magnetite (Fe_3O_4) forms a relatively compact iron shell during

reduction that strongly resists gas diffusion into the pellets, thus increasing reduction time (Ref 3). Pellets made from rich magnetite also disintegrate during reduction because of the high degree of swelling (Ref 4).

Sticking of the particles during reduction is perhaps the most serious problem encountered in fluidized-bed reduction of metal oxides, because it results in defluidization of the bed. The susceptibility of iron ore to sticking is a complex relationship between percent reduction, bed temperature, and gas velocity (Ref 5). By reducing low-gangue ore, Agarwal et al. (Ref 5) found that the susceptibility to defluidization is highest between about 620 and 730 °C (1150 and 1350 °F) for products reduced more than 90%. Below about 620 °C (1150 °F), the tendency to defluidize is minimal, but the resulting product is usually pyrophoric. At temperatures above 700 °C (1300 °F), the tendency to defluidize decreases.

Similar findings were observed by Bondarenko et al. (Ref 6) who established that the zone of fluidization expands by using larger pellets and increasing gas velocity and temperature from 550 to 900 °C (1020 to 1650 °F). Evidently, high temperature decreases surface activity of reduced particles, and sticking is decreased.

The extremely high surface area of direct-reduced iron contributes to rapid reoxidation (pyrophoric iron). The reoxidation of direct-reduced iron (the reaction of iron with oxygen and water) is a rapid process in which spontaneous ignition of iron powder may occur.

The tendency of direct-reduced iron to reoxidation depends on reduction temperature. The higher the temperature, the less the degree of reoxidation. Raw material composition also has an effect on the oxidation or degree of reactivity (Ref 7). According to Jensen (Ref 8), the presence of cementite (Fe_3C) has a passivating effect on oxidation at temperatures up to 150 °C (330 °F). At higher temperatures, this material oxidizes faster due to cementite decomposition. As discussed in Ref 8, high-temperature reoxidation may be prevented successfully by:

- Passivation during the manufacture of the product
- Keeping the product dry prior to use
- Avoiding contact with hot objects or other sources of thermal energy above about 200 °C (390 °F)

Advantages of reduction in a fluidized bed include:

- Effective interaction of gases and solids in the bed and high rates of heat and mass transfer between the solid and fluid allow high velocity of reactions.
- Fluidized-bed reduction is an isothermic process, which allows a narrow temperature range to be maintained.
- Gas recirculation is possible.
- Reduction in a fluidized bed can be converted into a fully automatic, continuous process.

Disadvantages include:

- Not all iron ore materials can be reduced in a fluidized bed because of the tendency of these particles to stick together.
- Particle size is limited from about 6.5 mm (0.25 in.) to a few microns, or about 0.001 in.
- Swelling of iron ore materials during reduction can result in disintegration and excessive loss of particles from the bed by the transport of material of the reaction zone (carryover).
- Pyrophoricity hinders storage and transport of reduced iron.
- A sharp temperature gradient exists near the bottom of the bed (Ref 9), which causes overheating of the grid.
- Countercurrent rates of fluid throughput are limited to the range over which the bed may be fluidized, the minimum fluidization velocity, or the carryover velocity.
- The hydrodynamics of fine materials is mismatched to the reduction process, because fluidization occurs at a gas velocity lower than that required for reduction.

Critical Fluidization Velocity. Critical velocity is the reduction gas velocity at which the fluidization of material is achieved without carryover from the reaction zone. References 10, 11, 12, 13, 14, 15, 16, 17, and 18 discuss empirical expressions for the parameters of the critical fluidization velocity. The derivations consider particle diameter, density of the solid and fluid, viscosity, and voidage.

Nu-Iron Process. Developed by the United States Steel Company in 1950 (Ref 19), the Nu-iron process uses fine iron ore (1.65 mm, or 0.065 in.) in the fluidized-bed reactor at temperatures of 600 to 700 °C (1110 to 1290 °F), which eliminates sticking and pyrophoricity. The reducing gas (73% H and 16% CO) is obtained by catalytic conversion of natural gas with steam. Before entering the reactor, iron ore is preheated to 375 °C (705 °F) by the off gas; then it is preheated to 925 °C (1695 °F) in a special furnace. The sponge iron, reduced to 90 to 95%, is briquetted and used in electric steelmaking furnaces.

The H-iron process was developed by Hydrocarbon Research Company and Bethlehem Steel Corporation. The process consists of reducing fine iron ore or mill scale (0.04 to 0.8 mm, or 0.0016 to 0.032 in.) by high-pressure hydrogen at 35 atm (515 psi) at a temperature of 540 °C (1000 °F).

Hydrogen is obtained by the water-steam or oxygen re-forming of natural gas. High hydrogen pressure is used to increase reduction velocity and decrease reactor size. To increase hydrogen utilization, three- and four-zone reactors are used, with capacities of 45 to 90 metric tons/year (50 to 100 tons/year). The reduced iron powder is annealed at 650 to 870 °C (1200 to 1600 °F) to render the powder nonpyrophoric. Depending on the reduction degree, the resulting reduced iron can be used for P/M structural parts (90 to 95% reduction degree) or in electric steelmaking furnaces (75% reduction degree).

ONIA Process. Developed in France, the ONIA (Office National Industriel d'Azote) process differs from the H-iron process. A low pressure of 5 atm (73.5 psi) is used. The composition of the reducing gas is 85 to 87% H and 14 to 16% CO. To avoid sticking, the process uses a reduction gas velocity significantly greater than the critical fluidization velocity. The sponge iron is used as a melt stock in electric furnaces and as a molding-grade powder.

Commercial Viability. As discussed in Ref 20, all of the fluidized-bed processes have been limited commercially because of sticking, high degrees of pyrophoricity due to extremely high microporosity, unsatisfactory quality of iron powder for molding applications, or a combination of these. Sticking can be eliminated by using a "semifluidized" bed in a reactor with pull-out grids (Ref 21). In this process, iron ore pellets (2 to 6 mm, or 0.08 to 0.24 in.) are reduced by the products of catalytic conversion of natural gas (35% H, 18% CO, 40% N).

Pellets are reduced in a two-stage fluidized-bed process. At first, a reduction degree of $r = 30\%$ is reached. After this stage, the fluidized bed sticks, forming a sponge cake. The second reduction stage ($r = 95$ to 99%) is accomplished in a semifluidized pulsating bed. Gas velocity during the impulse fluidization substantially exceeds the critical fluidization velocity, provided that the cake breaks and that there is a uniform gas supply. After cooling by nitrogen, the reduced iron is not pyrophoric because of high reduction temperatures of 800 to 870 °C (1470 to 1600 °F).

Laboratory experiments with a drum-type rotary fluidized bed also have shown methods of eliminating sticking (Ref 22). The advantages of fluidized-bed technology can be realized by use of an "improved" process that combines the fluidized bed with a mechanical or hydraulic device for breaking the sticking material. The technical feasibility to expand and develop fluidized-bed reduction processes depends on:

- Possibility to increase the temperature level of reduction with a simultaneous elimination of sticking and pyrophoricity
- Possibility to increase gas utilization efficiency
- Elimination of temperature gradient between the top and bottom of the fluidized bed

Production of Iron Powder*

Water Atomization

Atomization processes are widely used for making both iron and steel powders. Atomization consists of mechanical disintegration of molten metal stream into small droplets that are rapidly cooled by means of conductive or/and convective heat transfer. The disintegration of a liquid stream by the impingement of high-pressure jets of water, gas or oil is called water, gas or oil atomization, respectively. Other modified versions of atomization are centrifugal, vacuum, ultrasonic, rotating electrode process, plasma rotating electrode process, electron beam rotating process, and rotating disk atomization. These processes are discussed in more detail in the article "Atomization" in this Volume.

Atomization of molten iron is a flexible process that can be adapted to the production of low-carbon iron or alloy steel powders. Production of atomized iron powder is limited commercially to processes based on water atomization. Steel powders are also produced primarily by water atomization, although inert-gas atomization is used in production of some alloy steel powders (as discussed in the article "Production of Steel Powders" in this Volume).

This section focuses exclusively on water-atomized iron powders from the following four production facilities:

- Quebec Metal Powders process
- Domfer process
- Kobe/Kobelco process
- Kawasaki process

Production and properties of atomized low-alloy and high-alloy steel powders (by both water or gas atomization) are discussed in the article "Production of Steel Powders" in this Volume.

Production of Iron Powder*

The QMP Iron Powder Process**

In the Quebec Metal Powders (QMP) process, freshly refined high-purity iron passes through horizontal water jets, which produce granulated iron that is processed further by drying, grinding, decarburization, milling, and blending (Fig. 11). Because of the nature of the manufacturing process, the QMP iron powder grades (ATOMET 25, 28, 29, and 30) are highly porous powders with high compressibility for low-and medium-density P/M parts production.

Fig. 11 Schematic flow diagram of the QMP iron powder manufacturing process

The QMP process is based on conversion of high-purity, high-carbon iron received from the nearby smelter plant of QIT-Fer et Titane Inc. The liquid iron, desulfurized and recarburized at QIT to QMP specifications, is delivered as molten iron with a typical as-received analysis of:

- Carbon: 3.5 wt%
- Manganese: 0.008 wt%
- Silicon: 0.04 wt%
- Sulfur: 0.008 wt%

Due to the nature of both the ore deposit and the smelting process, the QIT iron is characterized by a low content of residual elements and an exceptional consistency of chemical composition. The high purity of the iron make it a well-

adapted starting material for the production of both steel and iron powders (Fig. 12). Steel powder QMP production is discussed in the article "Production of Steel Powders" in this Volume.

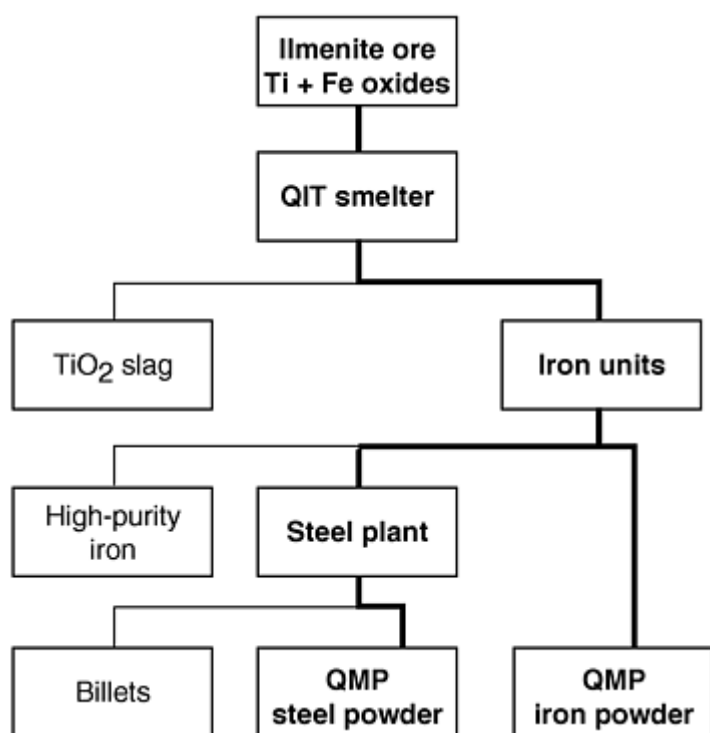

Fig. 12 Material flow through the QIT/QMP facilities for manufacturing iron and steel powders from ilmenite ore

Granulation. On arrival at the QMP iron powder plant, the hot metal is poured into one of two 82 metric ton (90 ton) induction holding furnaces. After temperature adjustment, the molten iron is poured from the induction furnace into a large tundish. The bottom of the tundish is equipped with four refractory nozzles that act as metering orifices. The streams of liquid iron flowing from the nozzles are disintegrated with high-pressure horizontal water jets directed into a large quench tank. Air drawn through ports in the quench tank cause the coarse granulated iron to be partially oxidized. The wet slurry from the granulation chamber is pumped to a magnetic dewaterer that feeds a vacuum filter to remove most of the water. The wet powder is then dried in a gas-fired rotary kiln dryer. The particle size of the as-granulated iron is typically -8 mesh. The carbon content of the iron drops to approximately 3% during granulation due to the partial oxidation of the granules that have an average oxygen content of about 5%.

Ball Milling. Coarsely granulated iron is then ball milled to powder size. The grinding is done in a Hardinge air-swept mill. At the discharge of the mill, the powder is pneumatically conveyed to a cyclone and discharged on a series of screens that allow grinding to be adjusted to specific particle size ranges. The ball-milled powder is analyzed for its chemical composition and particle size distribution and transferred to decarburization.

Decarburization. The granulated and ball-milled powder is stored in dedicated bins according to the oxygen and carbon contents of the product. Powder from various bins is fed into a blender to prepare chemically controlled feed for the decarburization furnaces. Quantities are determined so as to produce a blend of powder with a uniform oxygen-to-carbon ratio close to 2. The blended powder is then transferred to decarburizing furnaces. The continuous-belt furnaces, equipped with 120 cm (48 in.) wide solid belts, are maintained under a reducing atmosphere of dissociated ammonia. The ball-milled powder is fed onto the belt to form a bed approximately 25 mm (1 in.) thick and heated to temperatures in the range of 980 to 1040 °C (1800 to 1900 °F).

The carbon and the oxygen contained in the powder then reacts to form CO and CO₂ as reaction products. Hydrogen from dissociated ammonia contributes to further reduce the oxygen content of the powder. After cooling under a protective atmosphere, the product emerges from the furnaces as a loosely sintered spongy cake of pure iron, containing typically 0.05% C and 0.17% O.

Milling. At the discharge of the furnaces, the iron powder cake falls into a sawtooth crusher. The crushed cake is further processed in a series of attrition mills. The mills pulverize the cake into a powder of controlled particle size distribution and apparent density.

Blending and Packaging. The iron powder plant is equipped with a 36,000 kg (80,000 lb) capacity product blender in which individual batches of milled powder are homogenized to prepare large lots of powder of constant properties. For P/M applications, press-ready mixes are also manufactured by blending the plain iron powder with selected additives such as lubricants, graphite, and copper powders. The QMP iron powder is then packaged to be shipped worldwide.

Each powder lot is sampled and submitted to a series of quality control tests to certify that its chemical composition, physical characteristics, compressibility, green strength, dimensional change, and sintered strength meet customer requirements. The QMP quality system has been registered to ISO 9001 since 1993 and to QS-9000 since 1995.

Iron Powder Characteristics. The QMP iron powder process, because of its flexibility, allows high-quality iron powders to be produced for all the major applications of ferrous powders. The main use of QMP's iron powders is the production of structural parts by the P/M technique.

Because of the nature of their manufacturing process, ATOMET iron powders are highly porous, as illustrated in Fig. 13. This spongy structure and the high degree of purity of the product confer to P/M grades a combination of compressibility and green strength that make these products well suited for low-and medium-density applications. Typical chemical and physical properties of QMP iron powders (ATOMET 25, 28, 29, and 30) are given in Table 5. The porous nature of ATOMET iron powder particles also promotes sintering and permits rapid carbon pickup. Table 6 shows typical compaction behavior and sintered properties of iron powder grades.

Machinable P/M Grade. A patented machinable P/M grade, ATOMET 29M, has been developed specifically for P/M parts requiring machining. This product uses hexagonal boron nitride as a machinability enhancer. The boron-nitride enhancement allows a reduced drilling thrust force of P/M materials, even at high carbon contents (Fig. 14), and also contributes to increased tool life.

Fig. 14 Effect of boron nitride (ATOMET 29M) and carbon content on the thrust force measured when drilling sintered specimens

Special Powder Applications. Iron powders produced at QMP can also be tailored to meet the needs of a variety of non-P/M applications such as welding electrode coating, aluminum alloying, flame cutting, and scarfing. Also, special grades are manufactured for magnetic particle inspection, food additives, pharmaceutical applications, and carrier materials for photocopying machines.

The Domfer Process†

The Domfer process of making iron and steel powder was developed in 1952 at Iberville, Quebec. It consists of water atomizing a high-carbon iron melt to a granular "shot," which is then ball milled to powder size. The ground shot, which contains carbon, is mixed with ground mill scale (iron oxide) that contains oxygen. The carbon and oxygen are chemically combined in a belt furnace at sintering temperatures to form carbon monoxide gas, thus leaving a pure iron cake. The cake is disintegrated to powder size and further refined. A flowchart of the Domfer powder process in its present form which evolved from the original invention is given in Fig. 15.

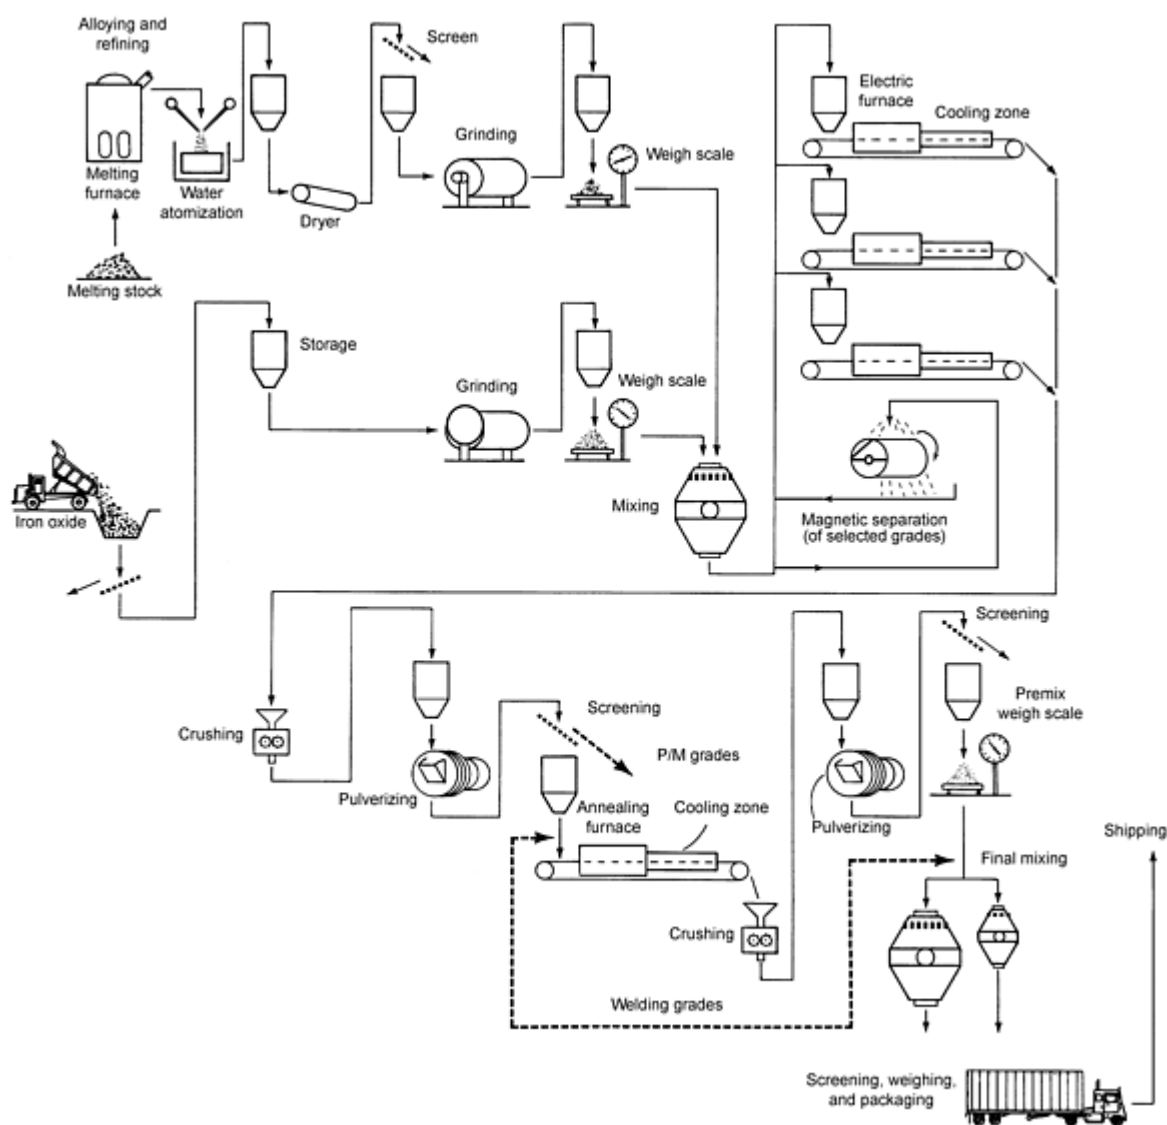

Fig. 15 Flowchart of the Domfer powder process

Melting and Refining. High-quality selected steel scrap is melted in a 12.7 metric ton (14 ton) coreless induction furnace with an addition of low-sulfur carbon to make a melt of approximately 3.5% C. For low-alloy steel powders, nickel and molybdenum also are added to the furnace.

Approximately 30% of the furnace charge is tapped into a ladle, deslagged, and desulfurized if necessary. Molten metal is poured through a tundish with bottom openings to control the size of the stream. The molten metal is disintegrated by

high-pressure jets of water to a granular material approximately 0.8 to 3.2 mm (0.03 to 0.12 in.) in size. This shot is dewatered in a cyclone and dried in a gas-fired dryer.

Grinding. Because the high-carbon shot is very brittle, it can be ground to the required powder size in an air-swept ball mill. Air flow controls the size of particles that leave the mill, and the powder is recovered from a combination dropout and cyclone separator. Selected mill scale, which is a by-product of rolling steel, is similarly ground to powder. The ground shot and mill scale are blended to achieve a carbon-to-oxygen ratio that results in decarburization and deoxidation, thus leaving essentially pure iron.

Decarburizing. The mixed powder is purified by magnetic separation (for selected grades) and laid on a steel belt that passes through an electrically heated furnace. The reaction between the high-carbon iron and mill scale occurs at a high temperature. The carbon monoxide gas that is generated provides both a reducing atmosphere and a furnace seal. The resulting pure iron sinters to a cake that is cooled to room temperature before leaving the furnace. The cake is reduced to powder size in an attrition mill and is screened to the desired size. It is then blended in a double-cone blender to the required specifications.

In the first stage of processing, carbon and oxygen levels are reduced to the specified values. This powder is suitable for the manufacture of welding rods and for lancing, cutting, and scarfing operations as well as for friction applications. Table 7 lists several iron powders of welding and friction grades that are produced by the Domfer process.

Annealing. A pure, soft powder is required by the P/M parts industry to reduce die wear and to lower the pressing tonnage required to attain the desired density. For this purpose, powder from the first stage is blended and fed to a second belt furnace. The conditions employed produce a very soft cake that can be reduced to powder size without work hardening. For selected P/M grades, decarburizing and annealing are conducted in a single-pass operation with modified furnace conditions.

Annealing typically reduces carbon to less than 0.01% and oxygen to less than 0.35%. It also produces soft powder with good compressibility. Powder premixes containing lubricant, graphite, and copper are blended to customer specifications. Table 8 lists several grades of compactable Domfer iron powders.

- (a) Of the base powder, admixed with 1% graphite, 2% copper and 0.75% lubricant.
- (b) Expressed as the green density obtained at 30 tsi compacting pressure.
- (c) Sintered at 1120 °C (2050 °F) for 30 min, under N₂ + H₂ atmosphere.
- (d) Hardness of these sinter-hardening grades depends on the cooling rate. It typically exceeds 20, 30, and 35 HRC for MP52, HP55HD, and MP56HD, respectively.

Quality Assurance. The Domfer process is a multistep operation that incorporates testing and blending between the stages to permit a wide range of powder qualities. The process sequence allows close control of uniformity from batch to batch. For most users, especially P/M parts manufacturers, this uniformity is the most important requirement.

For welding rod applications, essential properties to be controlled include carbon, oxygen, and sulfur content, screen analysis, apparent density, and flow characteristics. For additional P/M parts applications, sample bars are pressed and sintered to measure:

- Compressibility
- Green strength at this density
- Dimensional change during sintering
- Strength and hardness of the sintered bar

Domfer quality system has been registered as conforming to the ISO-9002 Standards since September 1994. QS-9000 accreditation is sought for 1998.

Production of Iron Powder*

Kobe/Kobelco Process

Kobe Steel Company and Kobelco Metal Powders produce water-atomized iron powder using a special V-jet water atomization process. Typical properties of four Kobelco water-atomized ferrous powders are summarized in Tables 9 and 10. Grades 500MA, 300MA, and 300ME achieve green densities of 6.8 g/cm^3 at 415 MPa (60 ksi). Grade 300MC has the highest compressibility, achieving a 6.90 g/cm^3 and 9.6 MPa (1.4 ksi) green strength at 415 MPa (60 ksi) with 0.75% zinc stearate (Fig. 16). Kobelco has also produced a 300MS grade iron powder with lower compressibility and green density (6.7 g/cm^3 at 415 MPa, or 60 ksi) but improved cleanliness, that is, low inclusion level (size: $50 \mu\text{m}$ max and area ratio: 0.03% max), which finds successful applications in hot powder forging of connecting rods and other automotive parts.

Kobe Steel Company also produces water-atomized iron powder grades such as:

- 300M offering high compressibility (6.9 g/cm^3 at 440 MPa, or 64 ksi)
- 300MH offering slightly higher purity and compressibility level (7.0 g/cm^3 at the same compaction pressure)
- 300NH achieving 7.1 g/cm^3 green density after extended reduction/annealing treatment (Ref 24)

Kawasaki Process

Kawasaki Steel Corporation has produced water-atomized iron powder (KIP 304AS grade) with high compressibility (7.05 g/cm^3 green density at 1% zinc stearate pressed at 490 MPa), higher purity, improved compactibility, lower inclusion content, high green strength, and low ejection force. These property improvements are achieved by the stricter selection of scrap, more rigorous refining in the electric arc furnace, extended high-temperature first annealing, and the incorporation of a second annealing.

Figure 17(a) shows the new Kawasaki process in comparison to standard water-atomization processing (Fig. 17b). Scrap is selected more carefully than for the standard operation, and the melt is atomized by water applied at a 30% lower pressure and 25% lower volume than in the standard operation. The reduced volume of atomizing water facilitates a higher degree of particle spheroidizing, which thus increases the apparent density of the primary powder. The lower water pressure results in an increase in average particle size to about $120 \mu\text{m}$, which is almost twice the size of primary powders from the standard process.

Fig. 17 Kawasaki manufacturing processes of atomized iron powders. (a) Optimized process of powders with high compressibility and green strength. (b) Standard process

The primary powder is annealed in hydrogen at a slightly higher temperature and a longer duration than the anneal in the standard process. After annealing, crushing and classification are executed. The first crushing in the new process is harder than that under standard conditions. In addition, a second anneal crush and classification sequence is carried out. The second crushing was softer, and the sieve size of the second classification was 44% larger than under standard conditions.

The purpose of this modified production process is to obtain powders that allow high compressibility, low ejection force, and high green strength during high-pressure pressing. High compressibility improves die life, while lower forces for ejection reduce the potential for cracking of more complex shapes during part compaction and transfer.

However, compressibility and high green strength require careful optimization of particle shape. Compressibility (or fill density) increases for spheroidized particles, while compact green strength depends on particle "entanglements" that are enhanced by more irregular shaped particles. Therefore, the compatibility of high compressibility and improved compactability (green strength) requires optimization of factors besides just particle shape. Green strength is enhanced by preventing excessive spheroidization, while compressibility is improved by other factors such as reductions in impurities and inclusions, reduced dislocation density, and greater coarseness in the particle size distribution. Accordingly, various manufacturing conditions are optimized in the Kawasaki process to obtain iron powder with a good combination of green strength and compressibility (Fig. 18) and low ejection force requirements (Fig. 19). The characteristics of powders A, B, C, and D are summarized in Table 11.

Table 11 Characteristics of secondary iron powder compared in Fig. 18 and 19

	Process conditions	Flow rate (s/50 g)	Particle size distribution, %						
			+180 μm	+150 μm	+106 μm	+75 μm	+63 μm	+45 μm	-45 μm

Production of Steel Powders

Introduction

STEEL POWDERS can be classified into three general types (Fig. 1) depending on the alloying process. The prealloyed powders are produced by melting and subsequent atomization, so that powder particles are of similar alloy composition. In contrast, admixed powders are alloyed during sintering, which requires sufficient diffusion and mass transport during the sintering process for homogenous alloying. The bonded or diffusion alloyed powders are the third type; they are similar to admixed grades, except that the powder fines for alloying are bonded to the surface of iron particle. This step reduces segregation and thus improves the chemical homogeneity of the alloy part after sintering.

Fig. 1 Schematic main alloying methods

The elements commonly used in powder metallurgy for the alloying of steel are carbon, nickel, copper, and molybdenum. Prealloyed steel powders with nickel and/or molybdenum are common because they have a low affinity for oxygen and only minor effect on compressibility. In contrast, manganese has a much stronger affinity for oxygen (Fig. 2), which requires better atmosphere control or higher furnace temperatures during sintering (see the article "Production Sintering Practices" in this Volume). In addition, manganese (due to oxide formation and significant solid-solution hardening) degrades powder compressibility of prealloyed steel powders (see the article "Compressibility and Compactibility of Metal Powders" in this Volume). Therefore, even though manganese is a powerful hardenability agent in steels, it is not commonly used in excess of 0.5% in prealloyed powders.

Fig. 2 Effect of alloying elements on residual oxygen content of prealloyed steel powders. Source: Ref 1

In steel P/M parts made from prealloyed or diffusion alloyed powders, carbon is usually mixed as graphite to form steel during sintering. Carbon has a strong hardening effect that significantly reduces compressibility (Fig. 3), which is why even many prealloyed steel powders have low residual carbon content. Impurities such as sulfur, nitrogen, oxygen, and phosphorus also have a detrimental effect on green strength (see the article "Compressibility and Compactibility of Metal Powders" in this Volume).

Fig. 3 Effect of alloy elements on compressibility

This article briefly reviews the production methods and characteristics of low-alloy, tool steel, and stainless steel powders. Emphasis is placed on atomized prealloyed powders. Numerous steel powder blends also are produced, but it would be difficult to summarize the various kinds of standard and custom mixes developed by powder producers for specific customer requirements. In many respects, ferrous blends will be influenced by the characteristics of the base iron powder, such as size distribution, particle shape, and composition. Figure 4 summarizes the particle size distributions from various iron powder production methods. Further information is provided in the article "Production of Iron Powders" in this Volume.

Fig. 4 Cumulative particle size distributions of some common iron powders. Source: Ref 2

Designations of Ferrous Powder Materials. Ferrous powders are commonly designated by specifications or standards such as MPIF standard 35 (Ref 3). A cross index of various P/M standards and specifications is listed in "Appendix 1: Mechanical Properties of Ferrous Powder Materials" in this Volume. Chemical compositions of ferrous P/M structural materials in MPIF standard 35 are listed in Table 1.

Table 1 Chemical compositions of ferrous P/M structural materials

MPIF designation	Composition range (min to max) ^(a) , wt%

- (a) MPIF standards require that the total amount of all other elements be 2.0%.
- (b) At least 1.0% Ni is admixed as elemental powder.
- (c) At least 2% Ni is admixed as elemental powder.

Ferrous Materials Produced from Elemental Powders. The standard MPIF designations for ferrous P/M materials manufactured from elemental iron powders include a prefix of one or more letters (the first of which is F to indicate an iron-base material), four numerals, and a suffix. The second letter in the prefix, which may be C for copper or N for nickel, identifies the principal alloying element (if one is specified); the percentage of that element is indicated by the first two digits. The third and fourth digits indicate the amount of carbon in the compacted and sintered part; the code designation 00 indicates less than 0.3%, 05 indicates 0.3 to 0.6%, and 08 indicates 0.6 to 0.9%. The suffix is used to indicate the minimum 0.2% yield strength of the as-sintered parts and the minimum ultimate tensile strength of heat treated materials in units of 6.894 MPa (1 ksi). The letters HT indicate heat treated. Ferrous materials produced from elemental powders include the iron and carbon steel, iron-copper and copper steels, and iron-nickel and nickel steels listed in Table 1.

Ferrous Materials Produced from Prealloyed Powders. In the case of prealloyed P/M low-alloy steels, the four-digit series described above is replaced with a designation derived from the American Iron and Steel Institute (AISI) coding system. An example would be FL-4605-100HT, where the prefix FL indicates a prealloyed low-alloy ferrous material and the four digits (4605) indicate a nickel-molybdenum low-alloy steel.

When a prealloyed P/M steel powder is modified with elemental additions, a three or four alpha-numeric designator is used. For example, FLN-4205 indicates a prealloyed steel powder (FL) with an elemental nickel (N) addition. Compositions of prealloyed low-alloy P/M steels are given in Table 1.

Sinter-hardened materials are also produced from prealloyed low-alloy steel powders containing nickel, molybdenum, manganese, and/or chromium as the major alloying elements. They may also contain elemental additions of copper and/or nickel. Due to these compositions, these materials may be quench hardened during the cooling cycle following sintering, thereby eliminating a subsequent heat treating step. Compositions of sinter-hardened P/M steels are given in Table 1. They are generally used in applications where high strength and wear resistance are required.

Diffusion-alloyed materials are powders in which the alloying elements of molybdenum, nickel, and copper are added as finely divided elements or oxides to the iron powder. They are then coreduced with the iron powders at an annealing step, resulting in firm attachment and partial diffusion of the elements to the iron. This partial alloying

increases hardenability compared to elemental mixtures; although for a given composition, hardenability of diffusion-alloyed material is not as high as a prealloyed material.

Diffusion-alloyed powders exhibit good compressibility. Diffusion bonding of the alloying elements also reduces the tendency toward powder segregation. These materials are also amenable to the warm compaction process. Compositions of diffusion-alloyed steels, which are indicated by the prefix FD in MPIF standard 35, are listed in Table 1.

Copper-Infiltrated Irons and Steels. Infiltration of ferrous P/M compacts with copper (10 to 20% Cu) increases their strength, hardness, fatigue resistance, and impact energy. Densities of $\geq 7.5 \text{ g/cm}^3$ are readily achieved. Compositions of infiltrated irons and steels, which are indicated by the prefix FX in MPIF standard 35, are listed in Table 1. Additional information is included in the article "Copper-Infiltrated Steel" in this Volume.

Production of Steel Powders

Steel Powders *

Fully prealloyed steel powders have been made by several manufacturers since the late 1960s. Because the alloying elements are homogeneously distributed throughout their powder particles, the overall compressibility is usually moderate-poor due to increased strength of the powder particles. This is a drawback when powders are pressed at room temperature as in traditional P/M process, but this characteristic becomes irrelevant for hot powder forging applications. That is why fully prealloyed powders are widely used in powder forging applications.

Both gas- and water-atomization processes are available to produce low-alloy steel, tool steel, 12% Cr steel, high-speed steel, and stainless steel powders. The method of production preference is determined to a large extent by the powder properties desired. Water-atomized powders generally are quite irregular in shape and have relatively high surface oxygen contents. Gas-atomized powders, on the other hand, generally are more spherical or rounded in shape and, if atomized by an inert gas, generally have lower oxygen (oxide) contents. There are, of course, exceptions in each type. For high-volume, low-cost production, water atomization generally is preferred over gas atomization, providing powder characteristics are compatible with the application. In spite of these important differences, the two processes are similar in many other respects.

Atomized ferrous powders must be softened by reducing annealing at 900 °C (1652 °F) in dry, purified hydrogen to facilitate pressing and to achieve the required green density and strength necessary for subsequent processing.

Production of Steel Powders

Plain and Low-Alloy Steel Powders

In the 1970s, a host of low-alloy steel powders was introduced by Hoeganaes, notably iron-phosphorus alloyed steel powders for high-performance P/M parts and soft magnets as well as for a range of Astaloy prealloyed water-atomized steel powders for powder forging and wear-resistant applications. More recently, prealloyed low-alloy steel powders containing nickel and molybdenum have now captured a permanent place in the manufacture of high-strength structural P/M parts. Silicon and manganese as well as manganese and chromium are also considered to have great potential as inexpensive alloying elements in the production of high-strength P/M steel components.

Hoeganaes has produced several water-atomized steel powders and designated them Ancorsteel grades such as 1000, 1000B, 1000C, 4600V, 85HP, and 150HP for high-performance applications. Table 2 lists the typical analysis and properties of base powder Ancorsteel 1000, 1000B, and 1000C grades. Ancorsteel 4600V has been shown to have a combination of high tensile and fatigue strengths. Table 3 illustrates the typical properties of Ancorsteel base powders 85HP, 150HP, and 4600V. Controlled additions of copper, nickel, and graphite into these Ancorsteel prealloy powders produce high sintered density and ultimate tensile strength. Accelerated cooling from sintering temperature (or sinter hardening) can be used to develop high-strength martensitic structures.

Quebec Metal Powders (QMP) water-atomized low-alloy steel grades include ATOMET 1001, 1001 HP, 4001, 4201, 4401, 4601, and 4701. High chemical purity, exceptional cleanliness, good apparent density and flow rate, high hardenability, and superior compressibility make them ideal material for high-performance P/M and powder forging applications. Typical chemical compositions of plain steel and low-alloy steel powders produced at QMP are shown in Table 4. The physical properties of all grades of Atomet low-alloy steel powders are similar as a result of well-controlled processing conditions. The typical physical characteristics of 1001 HP and 1001 plain steel powders are given in Table 5. While prealloying is generally known to reduce the compressibility of ferrous powders, Atomet low-alloy powders exhibit high compressibility characteristics (Table 6) due to the high purity of the liquid steel feedstock and specially developed atomization and annealing techniques.

Table 4 Typical chemical composition of Atomet steel powders

Atomet powder grade	Alloying elements, wt%				
	Mn	Ni	Mo	Cr	Other
Low-alloy grades					
4001	0.16	...	0.50
4201	0.28	0.45	0.60
4401	0.15	...	0.85
4601	0.20	1.80	0.55
4701	0.45	0.90	1.00	0.45	...
Plain steel grades					
1001 HP	0.06	(0.004 C, 0.06 O, 0.006 S)
1001	0.06	(0.003 C, 0.10 O, 0.008 S)

-100/+200 (-150/+75)	38	40
-200/+325 (-75/+45)	26	27
-325 (-45)	26	21

Table 6 Typical compressibility and green strength of Atomet low-alloy steel powders, mixed with 0.75% ZnSt

Property	Atomet grade				
	4001	4201	4401	4601	4701
Compacting pressure, at 6.8 g/cm ³ , MPa (tsi)	420 (30.5)	440 (32.0)	420 (30.5)	500 (36.2)	540 (39.0)

As in the case of plain steel powders, low-alloy steel powders can also be admixed with graphite and metallic additives such as nickel and copper powders using either regular or binder-treatment blending techniques. The combination of prealloyed and admixed elements allows a wide spectrum of strength and hardness to be achieved in the as-sintered or heat treated conditions. Due to its high content of alloying elements, Atomet 4701 is particularly well suited for sinter-hardening applications.

Mannesmann Demag has introduced water-atomized MSP4 prealloyed powder containing 4% Ni, 0.5% Mo, 0.01% C, and 0.15% O. Advantages of this powder are (a) its competitive price with heat treatable diffusion-alloyed steel powders based on Cr-Mn-Mo using vacuum annealing and (b) the use of traditional conveyor belt sintering at 1120 °C (2050 °F) together with rapid cooling to produce a homogeneous martensitic structure with close dimensional tolerance and without the need for sizing.

Mixing of 0.3 to 0.6% C as graphite and copper powder (up to 2%) with MSP4 compensates for shrinkage during sintering and volume increase during martensitic transformation. This powder is finding application as high-performance automotive cams and synchronizer hubs (Ref 5).

Kobelco ultrahigh-pressure water-atomized steel powders have high purity, consistent high quality, good compressibility, and compactibility. They are available for a wide range of industrial applications. Grades include 300MC, 300ME, 300MS, and 4600A (Table 7).

Kawasaki Steel Corporation has developed a grade of low-alloy steel powder, 4600ES, which is suitable for the production of high-density and high-strength P/M components through double-pressing/double-sintering and heat treatment operations. Grade 4100VS powder (Table 8) obtains green density of 7.15 g/cm³ at compaction pressure of 690 MPa. This is attributed to the low oxygen, carbon, and nitrogen contents. By including a vacuum reduction annealing method, green strength is better than 6.91 g/cm³ for an earlier grade of 4100. Table 8 lists the compositions of KIP alloy steel powders.

Table 8 Compositions of Kawasaki (KIP) prealloy and diffusion-alloyed powders

Production of Steel Powders

Tool Steel Powders

The basic problem with high-speed steels is their strong tendency for segregation, which results in a fairly coarse and nonuniform structure; this, in turn, affects the safety in heat treatment, makes the grinding operation more difficult, and limits the toughness. The use of proper P/M technique has solved this problem.

Tool steel powders are produced by gas- or water-atomization methods (as discussed in more detail in the section "Tool Steel Atomization" in this article). Gas (argon or nitrogen)-atomized tool steel powders have particles that are spherical in shape with high apparent densities (about 6 g/cm³), which thus requires hot or cold isostatic pressing consolidation. Standard and proprietary compositions of gas-atomized tool steel powders are given in Table 9.

Table 9 Nominal compositions of gas-atomized tool steels

Water-atomized tool steel powders have irregularly shaped particles and are suitable for conventional die compaction and sintering to higher theoretical density. Typical compositions and powder properties of water-atomized high-speed steel powders are given in Table 10. Small (0.15 to 0.2%) amounts of graphite sometimes are added to the powder to adjust or increase carbon content of the sintered product.

(a) Green properties determined using die wall lubrication

Powder cleanliness is important for tool steel powders. Powder producers provide high standards of cleanliness through campaigning of heats, dedication of production equipment, use of powder cleaning equipment, and meticulous housekeeping. Producers include Powders Ltd., Davy Loewy, and Edgar Allen Tools Ltd. in the United Kingdom and CMI in the United States, who have developed high-speed steel (HSS) powder production technology based on water-atomization process. On the other hand, Uddeholm in Sweden, Crucible Inc. in the United States, and Kobe Steel in Japan have produced HSS powders by inert-gas-atomization process.

The Kobe atomization process involves high-purity, high-pressure gas atomization of molten steel from the tundish into a rapidly solidified powder with a fine homogeneous carbide or carbonitride structure, heating in a nitriding furnace, and blending in order to homogenize contained nitrogen. It is then transformed to a mild steel can, evacuated, and sealed (Fig. 5). This nitrogen-containing HSS powder contains 0.6 to 1.4% C, 0 to 1% N, 4% Cr, 6% Mo, 6% W, and 3.5% V.

Fig. 5 Flowsheet of the Kobe high-speed steel powder manufacturing process

The ASEA STORA process (ASP) for the high-speed and tool steel powders was introduced in the 1970s. This uses inert gas atomization of prealloyed melt to produce relatively coarse, essentially spherical metal powders. In the new horizontal design, the melt is disintegrated into very small drops by a gas jet. The droplets are flung horizontally where they cool and solidify very rapidly into spherical powder particles. The powder is then screened prior to leaving the atomization chamber and finally poured directly into a storage container.

A limiting factor for HSS material is the size of the fracture-initiating defect to which the strength level can be directly related. The smaller the defect the higher the strength according to the equation:

$$\sigma = \text{constant} \times \left(\frac{K_{Ic}}{\sqrt{d}} \right)$$

where K_{Ic} is the fracture toughness of the material and d is the size of the critical size defect. In the ASP-processed material, the harmful effect of large carbide is nonexistent (Ref 6).

Production of Steel Powders

Diffusion-Alloyed Powders

The demand for making high-strength, high-ductility P/M parts through single pressing and sintering has led to the development of several types of composite-type, partially prealloyed steel powder containing copper, nickel, and molybdenum. They exhibit high compressibility and are heat treatable for maximum properties. They represent a real breakthrough in iron-base sintered alloys (Ref 7).

The production of these powders involves the heat treatment of a mixture of iron powder and fine metal alloy powders in reducing atmosphere. Diffusion bonding of the alloying elements into the iron powder particles takes place during this process (Ref 8).

Diffusion-alloyed steels were introduced in the late 1970s to bridge the gap between premix and prealloyed steels. The premixes were produced by mixing elemental alloying powders, such as nickel, copper, and molybdenum with high compressibility pure iron-base powders. Although the premixes were able to achieve high green density, the alloying powders were likely to segregate and not completely alloy during sintering, and the resultant mechanical properties were insufficient for high-strength sintered P/M parts. In contrast, the prealloyed steel powders produced a homogeneous structure, but were much less compressible than the premixed powders.

The diffusion-alloyed steel powders overcome the specific limitations of both premixed and prealloyed powders by combining the compressibility of a pure iron powder with the lack of segregation of a prealloyed powder. The diffusion-alloyed steel powders have been successfully used to produce high-strength sintered P/M products through single-press/single-sinter processing.

The advantages of diffusion-alloyed steel powders are (Ref 8):

- Maintenance of high inherent compressibility of the base iron
- Increased green strength
- Reduced risk of alloy segregation and dusting during transportation of the powder mix
- Homogeneous distribution of alloying elements
- Good sinterability
- Outstanding stability of this composite-type base powder

Diffusion-alloyed powders have also led to the elimination of double-pressing/double-sintering and sizing because of the high hardness obtained in the sintered condition (Ref 8).

Commercial Grades. Several different trademarks are used for diffusion-alloyed grades, and some of the more prevalent grades are briefly described below.

Distaloy grades are produced by Hoeganaes and Hogänäs including Distaloy grades SA, AB, SE, SH, AE, AG, 4600A, and 4800A. The Distaloy grades are produced using either sponge iron or atomized Ancorsteel 1000 B powders and varying amounts of Cu, Ni-Cu, Ni-Mo-Cu, and Ni-Mo as alloying elements for bonding to the surface of the iron powder particles. Distaloy AG is based on the supercompressible iron powder (ASC 100.29) atomized iron powder with 8% Ni and 1% Mo additions. Mixed with 0.5% graphite and lubricant, Distaloy AG can produce parts (after single pressing at 600 MPa and single sintering at 1150 °C, or 2100 °F), with a sintered density of 7.32 g/cm³, a tensile strength of more than 1000 MPa, elongation of 4%, and hardness of 320 HV20 without heat treatment.

Distaloy 4800A is a diffusion-bonded steel powder with 4% Ni, 0.5% Mo, and 1.5% Cu. Mixed with 2% Ni, 0.3 to 0.8% graphite, and 0.75% Acrawax using Ancorbond process, it can produce column tilt levers by double pressing to a density of 7.3 g/cm³ with impact and hardness values exceeding the specified minimum (27.2 J and 68 HR15N, respectively). Carburizing treatment, followed by tempering at 232 °C (450 °F), imparts a wear-resistant surface. This P/M part only requires honing of the pivot hole to meet the specified tolerance.

Sigmaloy grades are diffusion-alloyed powders produced by Kawasaki. The composite-type alloyed Sigmaloy 415S and 2010 steel powders use water-atomized pure iron powder as the base material (see Table 8 for composition). Sigmaloy 2010 can achieve tensile strength of 1500 MPa, an impact toughness of 21 J, a rotating bend fatigue strength of 460 MPa and a contact fatigue strength of 2560 MPa after normal pressing, sintering, and case hardening. Tensile strength of 1920 MPa with an impact strength of 53 J is obtained after double-pressing/double-sintering, bright quenching, and tempering (Ref 9). The increased properties of sintered compacts made from Sigmaloy 2010 are attributed to the strain-induced martensitic transformation of nickel-rich retained austenite in the sintered compact during tensile or fatigue tests. Sigmaloy 2010 and 415S steel powder find applications in automobiles as valve guides, shock absorber parts, oil pump rotors, timing pulleys, and so forth (Ref 8).

Atomet diffusion-bonded powders are produced by Quebec Metal Powders Ltd. The typical properties of Atomet diffusion-bonded powders are given in Table 11. Because of the multiphase structure of materials made from diffusion-bonded powders, these exhibit excellent dynamic properties. Like other diffusion-alloyed powders, they are well suited for high-density applications where impact and fatigue resistance are critical.

Table 11 Typical properties of Atomet diffusion-bonded powders

Property	Atomet grade	
	DB46	DB48
Chemical analysis, %		
Carbon	0.005	0.005
Oxygen	0.10	0.10
Sulfur	0.007	0.007
Manganese	0.16	0.16
Molybdenum	0.50	0.50
Copper	1.45	1.45
Nickel	1.80	4.00
Physical properties		
Apparent density, g/cm³	3.00	3.00
Flow rate, s/50 g	24	24
Sieve analysis, U.S. mesh (microns), %		
+70 (+212)	Trace	Trace
-70/+100 (-212/+150)	9	9
-100/+200 (-150/+75)	38	38
-200/+325 (-75/+45)	29	29
-325 (-45)	24	24
Compacting pressure at 7.0 g/cm³, MPa (tsi)	540 (39.0)	545 (39.5)
Green strength at 7.0 g/cm³, MPa (ksi)	11 (1.6)	11 (1.6)
Dimensional change from die size^(a), %	+0.18	+0.01
Transverse rupture strength^(a), MPa (ksi)	1275 (185)	1450 (210)

(a) Atomet DB powder + 0.6 graphite + 0.75 ZnSt, pressed to 7.0 g/cm³, sintered 25 min at 1120 °C in nitrogen-base atmosphere

Mannesmann Demag's new diffusion-alloyed "master alloy" grade ULTRAPAC-20 Cu gives a segregation-free copper distribution. The copper content can be adjusted by mixing ULTRAPAC-20 Cu with plain iron powder (Ref 10).

Production of Steel Powders

Other Alloying Methods

Admixing. Press-ready mixes contain all the necessary alloying additions for powder users. To preserve premix uniformity against the natural tendency to demix during handling and subsequent processing, various proprietary mixing processes use patented binders to bond additives to the base powders. The benefits of premix processing with binders are:

- Improved (or uniform) flow rate and better die filling while retaining similar green strength
- Potential for improved productivity
- Reduced variability in the sintered properties
- Opportunities for new alloy development
- Utilization of fine particle additives
- Potential for achieving increased P/M part densities and weight control without the need to resort to double-pressing/double-sintering techniques

Hoeganaes QMP, and Kawasaki have developed these "segregation-free" premixed powders by bonding graphite and other alloying additives to the surface of iron powder.

Mechanical Alloying (MA). In the MA process, composite metallic (or ceramic) powders are produced by simultaneous and repeated sequences of extensive plastic deformation, cold welding, and fracturing of a mixture of metallic and alloying ingredient particles during a dry, high-energy (attrition, vibratory, or large-diameter tumbler) ball-milling process.

The mechanically alloyed powders are characterized by dense, intimate mixing of constituent metals on a fine scale, homogeneous with a grain-refined (submicron grain size) microstructure, extended solid solubility, and formation of nonequilibrium phases. These particles have irregular shape, suitable for high packing density during compaction, and, in addition, they are free of the interdendritic microsegregation and pores that are occasionally encountered. This results in a unique combination of high strength and corrosion resistance. Another advantage is the production of amorphous alloys where an extended range of compositions can be processed, which is not possible by rapid solidification.

Mechanical alloying is the most successful method for the production of high-temperature creep-resistant fine (submicron) oxide-dispersion-strengthened (ODS) iron-base superalloys, amorphous iron-titanium, and iron-tantalum alloy powders. Further information is contained in the article "Mechanical Alloying" in this Volume.

Rapid Solidification Process (RSP). In RSP, the local solidification time is reduced with increasing cooling rate. Typically, the cooling rates of conduction processes range between 10^6 and 10^8 °C/s (1.8×10^6 and 1.8×10^8 °F/s), whereas the convection processes may be limited to the range 10^4 and 10^6 °C/s (1.8×10^4 and 1.8×10^6 °F/s).

Important attributes of RSP are: increased homogeneity, highly refined microstructure and second-phase particle refinement, extended solid-solubility limit (i.e., alloying flexibility), and formation of unique nonequilibrium crystalline

and noncrystalline (amorphous or glassy) metastable phases that have significant influence on the properties and structural engineering applications of alloys.

Rapidly solidified low-alloy steel powders with a fine homogeneous structure and dispersion of fine, stable sulfide and oxide inclusions such as MnS, VS, SiO₂, MgO, and Al₂O₃ have been produced for hot consolidation processing to high-strength and ultrahigh-strength P/M parts. This enhancement of mechanical properties is attributed to the retention of fine grain size during austenitizing at high temperatures because of effective pinning of grain boundaries by finely dispersed, stable inclusions. Production of stress-corrosion-resistant NiMoLa ultrahigh-strength steel via RSP is another landmark in the development of high-performance P/M parts (Ref 11). The composition of this steel is similar to 4340 NiCrMo steel where chromium is replaced by higher concentration of molybdenum (1.5% instead of 0.25%), and lanthanum (as LaNi₅) is introduced into the melt to balance phosphorus and sulfur to promote stable fine LaPo₄ and La₂O₂S inclusions (Ref 12).

Other potentials in RSP technology include the development of amorphous soft magnetic materials, amorphous ferromagnetic Fe-B-Si alloys for transformer applications, crystalline soft magnetic Fe-B-Si-Al alloy (Ref 13), and hard magnetic alloys based on crystalline Fe-Nd-B alloy (Ref 14).

Production of Steel Powders

Stainless Steel and High-Alloy Powders

E. Klar and P.K. Samal, OMG AMERICAS

Most stainless steel and other high-alloy powders are made by water atomization or by inert gas and centrifugal atomization. Information on these processes can be found in the article "Atomization" in this Volume. Water-atomized powders generally are of irregular particle shape and widely used for cold compaction and sintering. The densities of the resulting sintered parts are typically below about 95% of theoretical. It is for this reason that dynamic mechanical properties as well as a number of physical properties are below those of their fully dense counterparts. For the same reason, such parts often can tolerate greater levels of interstitials, although the tendency here is toward lower levels of interstitials in both powders and sintered parts.

Gas-atomized powders generally have spherical particle shape and require consolidation techniques such as hot isostatic pressing, extrusion, or metal injection molding. The properties of parts produced by these methods are generally equal and sometimes superior to their ingot metallurgy (I/M) counterparts. For these materials, the control of interstitials usually is very important. The superior properties derive from a more uniform and cleaner microstructure as a result of the rapid quenching inherent in the powder-making processes and from the careful control of contamination with ceramic and other materials during powder making and consolidation.

Three important classes of high-alloy powders are discussed in more detail in this section. They include stainless steel powders, tool steel powders, and superalloy powders. Aluminum alloy powders are discussed in a separate article in this Volume.

Stainless Steel Powders

Water-Atomized Stainless Steel Powders. Early experiments concentrated on producing stainless steel powders from elemental components and from alloy powders by sensitization embrittlement and grinding of stainless steel sheet. Water atomization became the established process in the 1950s for producing stainless steel powders for conventional die compaction and sintering. Over the years, slight modifications to the existing wrought compositions led to improved compacting properties. Recently, further modifications in composition, combined with processing precautions, have led to improvements in corrosion resistance.

Melting of virgin raw materials is performed in open air or vacuum induction furnaces. Low manganese concentrations ($<0.3\%$) and deoxidation with ferrosilicon to achieve 0.7 to 1.0% Si in the alloy prevent excessive oxidation of the powder during water atomization in an inert gas (nitrogen)-purged atomization chamber. Typical water pressures for producing predominantly - 80 mesh powder are about 14 MPa (2 ksi).

Compositions and powder properties of commercial grades of stainless steel powders are given in Table 12. These powders normally are used in the as-atomized condition, although martensitic and ferritic grades may be annealed to improve green strength and compressibility. Particle shape (Fig. 6) and other powder characteristics are controlled to produce powders with apparent densities ranging from 2.5 to 3.2 g/cm³, adequate green strength (Fig. 7a), and good compressibility (Fig. 7b). In Fig. 7(a) and 7(b), the higher green densities are typically obtained for the lower alloyed grades. Also, low contents of interstitials (carbon, oxygen, nitrogen) improve green strength, compressibility, and corrosion resistance. For applications requiring high green strength, Acrawax or stearic acid, instead of lithium stearate, may be used as lubricant. However, the improvement of green strength comes at the expense of reduced compressibility.

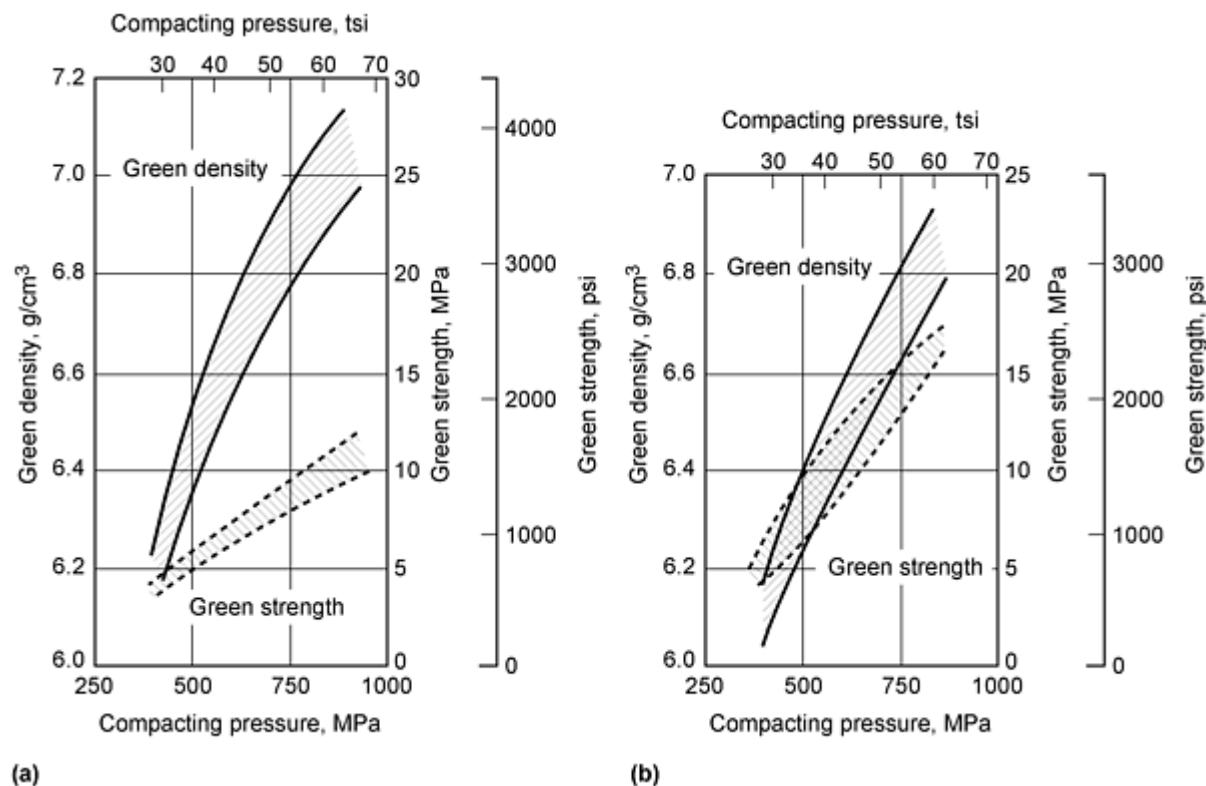

Fig. 7 Typical compressibility and green strength ranges of stainless steel powders. Die lubricant, 1% lithium stearate. (a) Austenitic grades. (b) Ferritic and martensitic grades

To ensure that a stainless steel powder is free from contamination with iron, low-alloy steel, and other powders capable of producing galvanic corrosion, the copper sulfate or Ferroxy test may be applied. Details of these tests are described in the section "Sintering of Stainless Steel" in the article "Production Sintering Practices" in this Volume.

Gas-Atomized Stainless Steel Powders. Gas (nitrogen and argon)-atomized stainless steel powders have particles that are spherical in shape (Fig. 8). These powders have high apparent densities of about 5 g/cm³ and excellent flow rates. They require special methods of consolidation such as hot isostatic pressing, cold isostatic pressing, or extrusion. Oxygen contents are similar to those of wrought stainless steels. Much emphasis is being placed on avoiding cross-contamination and contamination with ceramic (slag) particles. The latter are controlled to very small levels of concentration as well as to very small sizes, typically less than 25 μ m and preferably less than 10 μ m. Such control is essential if fatigue life, toughness, and other properties are to be maximized and exceed those of I/M materials.

Fig. 8 Scanning electron micrograph of nitrogen-atomized 316L stainless steel. 65×

Commercially available grades include AISI grades 410, 440C, 446, 304L, 304, 347, 316L, 316, and 317. Chemical compositions are similar or identical to conventional wrought grades. Special compositional adjustments are unnecessary due to the absence of water during atomization and due to the special consolidation methods.

Production of Steel Powders

Tool Steel Atomization

Powder metallurgy tool steel development in the United States began in the 1970s. Success of P/M tool steels is based mainly on the uniform microstructure obtainable, compared to wrought and conventionally produced products. Superior uniformity of composition leads to excellent toughness and less distortion during heat treatment. Tool life is increased. Reduced grinding costs due to superior grindability in comparison to conventional tool steels is due to the finer and more uniformly distributed carbides.

As in the case of stainless steel powders, both water-atomized and inert-gas-atomized tool steel powders are available. They also differ in particle shape and chemical composition and require different consolidation techniques, as previously noted in the section "Tool Steel Powders."

Water-atomized tool steel powders are produced by induction melting of virgin raw materials and/or scrap. These powders have irregularly shaped particles (Fig. 9) and are suitable for conventional die compaction and sintering to high or theoretical density. Unlike stainless steel and low-alloy steel powders, water-atomized tool steel powders are vacuum deoxidized and vacuum annealed to reduce their oxygen contents and improve their compacting properties. Deoxidation occurs at elevated temperature as a solid-state reaction between the oxygen and carbon within individual particles, in which the oxygen content of the powder is lowered from about 1500 to 3000 ppm to below 1000 ppm.

Fig. 9 Scanning electron micrograph of water atomized high-speed tool steel

Annealing lowers hardness from 700 to less than 300 HV. Further reduction of oxygen to less than 100 ppm occurs during sintering. Water-atomized tool steel powders can be pulverized for very fine particle size and accelerated sintering characteristics.

Commercially available water-atomized tool steel powders include several high-speed steels (M2, M3/2, M4, M35, M42-Si, T15, T42) and hot- and cold-work steels (D2, H13). Typical compositions and powder properties of some of these powders are given in Table 10. Small (0.15 to 0.2%) amounts of graphite sometimes are added to the powder to adjust or increase carbon content of the sintered product.

Water-atomized tool steel powders may also be added to low-alloy iron powders to enhance their wear resistance (Ref 15).

Figure 10 illustrates the microstructures of water-atomized T15 tool steel before and after annealing. Annealing depletes the carbon from the martensitic matrix by forming carbides.

Fig. 10 Microstructures of water-atomized T15 tool steel powder. (a) As-atomized. (b) After annealing

Gas-atomized tool steel powders have spherical particle shape (Fig. 11) and are usually consolidated to full density by HIP, extrusion, or MIM. In the early years of this technology, emphasis was placed on small carbide size and uniform microstructure, as well as the capability to make higher-alloyed compositions using P/M techniques. In recent years, the control and minimization of oxide inclusions have been in the foreground of technical efforts. Improvements in melting, that is, electroslag heating, slag separation, and atomizing (Ref 16, 17) have led to still lower oxygen levels of less than 50 ppm, smaller inclusion size (the goal is $<10\ \mu\text{m}$) and the reduction of other defects (e.g., argon porosity). Closed processing of the powder minimizes macroinclusions. The refined microstructure of the powder is retained in the consolidated products and accounts for marked improvements in toughness, bend strength, fatigue life, and other properties. Table 9 summarizes widely used grades of gas-atomized tool steels.

Production of Steel Powders

Superalloy Powders

Superalloy powders are typically made by vacuum induction melting and filtering of high-purity raw materials followed by inert atomization such as argon gas or centrifugal atomization. The presence in superalloys of elements with very high oxygen affinities (i.e., titanium, aluminum, hafnium, and zirconium) prohibits water atomization because the oxides formed during atomization (via $\text{Me} + \text{H}_2\text{O} \rightarrow \text{MeO} + \text{H}_2$) are nonreducible and in part responsible for the so-called prior particle boundaries (PPBs) in the consolidated products with their detrimental effects on mechanical properties. Even with inert atomized powders, PPBs can be present and must be dealt with. Furthermore, superalloys with large amounts of second-phase ' are practically unworkable by conventional hot-working techniques for large parts and are therefore made by P/M techniques.

Cleanliness, minimization of the amount and size of ceramic inclusions (e.g., by screening the powder, Ref 18), and other defects (i.e., inert gas porosity, Ref 19) are even more important than is described in the previous section for high-performance P/M tool steels. In a recent paper (Ref 20), combining electroslag refining with atomizing and/or spray forming is described and shown to produce very clean materials. To facilitate the achievement of these demanding requirements, manufacturers of superalloy parts, unlike manufacturers in the conventional powder metals industry, often make their own powders.

The goal of combining sulfidation and oxidation resistance with ever-increasing elevated-temperature strength (e.g., in gas turbine engines) for this class of P/M materials has led, in recent years, to increasing efforts and use of ODS superalloys. The invention of mechanical alloying in 1966 by Benjamin (Ref 21) permits the introduction of a finely dispersed oxide into even very highly alloyed and reactive-element-containing alloys.

Mechanically alloyed powders are made by dry, high-energy milling of blends of metal powders, master alloys, and refractory compounds. The starting powders can be relatively coarse, for example, 50 to 100 μm average diameter. The dispersion of the oxides (typically yttria or alumina) after milling can have uniform interparticle spacings of less than 1 μm . The amount of oxide added to superalloys ranges from about 0.4 to 1.5 wt% (1 to 2.7 vol% for yttria).

Table 13 summarizes both conventional and yttria-dispersion-strengthened P/M superalloy compositions. For details on processing and properties of consolidated materials, see the article "Powder Metallurgy Superalloys" in this Volume.

Production of Copper Powders

David F. Berry, OMG AMERICAS; Erhard Klar, Consultant

Introduction

THE SELF-LUBRICATING BRONZE BEARING, invented in the 1920s, and its subsequent development brought about the commercial production of copper powders. The first large-scale production processes were oxide reduction and electrolytic deposition. Electrolytic copper powders enabled the development of copper-graphite electrical brushes and copper-base friction materials in the 1930s. Copper powder made by the cementation process was also used in copper-base friction materials for a period of time, but ceased in the 1970s. Other hydrometallurgical processes for copper powder production were developed in the 1950s and 1960s. Some powders were commercially used for a number of years. Further growth of copper powder production took place with the development, during World War II, of the ferrous structural parts industry, which uses copper additions for alloy strengthening. In the 1950s, production of copper and copper alloy powders by water atomization became commercially significant. By the early 1980s, competition from oxide-reduction and atomization processes caused commercial production of electrolytic copper powder to cease in the United States, but it is still commercially produced in Europe and Asia, where water atomization is the main competitive commercial process.

This article describes the fundamentals of the four processes used for the production of copper powders, the physical and mechanical properties of the powders produced, and the applications of the copper powders. More detailed information is found in the articles of this Volume devoted to the individual powder-producing methods.

Production of Copper Powders

David F. Berry, OMG AMERICAS; Erhard Klar, Consultant

Production of Copper Powder by the Reduction of Copper Oxide

Reduction of copper oxide is the oldest and (in the United States) still one of the main commercial processes for making copper powder, along with water atomization. In this process, particulate copper oxide is converted to copper at elevated temperature by reducing gases. The product, a sintered porous cake, is then milled to a powder. The starting material for reduction was originally copper millscale and cement copper. However, as demand for copper powder exceeded supply and higher purity was required, particulate copper of high purity (chopped scrap or atomized copper) was oxidized to form cuprous or cupric oxide or a mixture of both.

Melting of Copper

In recent years, the increasing emphasis on purity has supplanted both copper mill scale and cement copper as the starting materials for making oxide-reduced copper powders.

Copper melting is performed in both fuel-fired and induction-heated furnaces. Strong oxide formers, such as aluminum and silicon, are kept low; thus, the molten metal remains fluid and can be poured without difficulty. Aluminum and silicon oxides also make the powder less compressible and very abrasive. In addition, lead and tin cause problems in pouring the melt due to buildups and clogging in the furnaces and nozzles.

In some applications of copper powder (for example, metal-graphite brushes and friction parts), good electrical or thermal conductivity is important. For this reason, impurity levels must be kept low. The detrimental effect on electrical conductivity caused by some impurities that are present in solid solution is shown in Fig. 1. Thermal conductivity is similarly dependent on the impurity content.

Fig. 1 Effect of impurities in solid solution on electrical conductivity of oxygen-free copper

Atomization and Shotting of Copper

Large-scale atomization of copper usually is conducted in air as a continuous process. Liquid copper may be atomized directly from a tube in the side of the furnace wall or through a tundish. Both air and water may be used as atomizing media, and horizontal atomization with high-pressure air into a rotating drum eliminates the need for drying of the powder. For details of atomization, including nozzle configurations and pressure relationships, see the article "Atomization" in this Volume.

Scanning electron micrographs of air-atomized and water-atomized copper powders are shown in Fig. 2. The water-atomized powder has a more irregular particle shape, and its oxide content is somewhat lower. At this process stage, however, particle shape is not very important. The coarse shot-type powder that is produced by low-pressure air or water atomization (Fig. 3) is the typical starting material for the pure copper oxide process.

Fig. 2 Scanning electron micrographs of copper powder. (a) Air atomized. (b) Water atomized

Fig. 3 Air-shotted copper

Oxidation of Copper Powder

Oxidation of air-atomized, water-atomized, or shotted copper is performed to radically change the shape of the powder and thus enhance control over the various engineering properties of parts made from the powder. Completely oxidized and reduced powders with a wholly spongy (porous) structure and entirely solid powders, as typified by a gas-atomized powder, constitute the extremes of available copper powders. Partial oxidation results in intermediate structures.

The oxidation of copper is a well-known process. There are two copper oxides, the red cuprous oxide, Cu_2O , and the black cupric oxide, CuO . At high temperatures and for the so-called thick film range, oxidation follows the parabolic rate law, in which film thickness (y) increases with the square root of time ($y = \sqrt{Kpt+c}$). At low temperatures, linear, logarithmic, and cubic oxidation rates have been observed, depending on the history of the oxide. Free energies, heats of reaction, and rates of copper oxide formation are shown in Table 1.

Table 1 Free energies, heats, and rates of copper oxide formation

$2(\text{Cu}) + \frac{1}{2}(\text{O}_2) = \text{Cu}_2\text{O}$ exothermic
$\Delta G = -41,166 - 1.27 \times 10^{-3} T \ln T + 3.7 \times 10^{-3} T^2 - 1.80 \times 10^{-7} T^3 + 27.881 T$
$k = 957 e^{-37,100/RT} \text{ g cm}^{-4} \text{ h}^{-1}$
$\text{Cu} + \frac{1}{2}(\text{O}_2) = \text{CuO}$ exothermic
$\Delta G = -37,353 - 0.16 T \ln T - 1.69 \times 10^{-3} T^2 - 9 \times 10^{-8} T^3 + 25.082 T$
$\Delta H = -38,170 + 1.30 T + 0.99 \times 10^{-3} T^2 + 0.57 \times 10^{-5} T^3$
$\text{Cu}_2\text{O} + \frac{1}{2}(\text{O}_2) = 2\text{CuO}$ exothermic
$\Delta G = -33,550 + 0.95 T \ln T - 3.75 \times 10^{-3} T^2 + 22.340 T$
$\Delta H = -35,710 + 3.28 \times T - 0.40 \times 10^{-3} T^2 - 0.20 \times 10^{-5} T^3$
$k = 0.0268 e^{-20,140/RT} \text{ g cm}^{-4} \text{ h}^{-1}$

ΔG is free energy; ΔH is heat; values of ΔG and ΔH are given in calories per gram mole; k is a rate constant mathematically derived; T is the absolute temperature, degrees kelvin; R is the absolute gas constant; \ln is the natural logarithm (base e , where $e = 2.7182$).

In commercial practice, oxidation or roasting of copper powder normally is done in air at temperatures above 650 °C (1200 °F). Oxidation in rotary kilns or fluidized beds provides faster oxidation rates by increasing the contact area between powder and oxidizing gas. However, due to the strongly exothermic nature of the oxidation reactions, these operations are more difficult to control than roasting in a belt conveyor furnace.

Grinding of Copper Oxide. Both oxides of copper are brittle and easy to grind to -100 mesh powder. The oxide particles themselves are porous. Figure 4 shows oxidized shot before and after grinding.

Fig. 4 Micrographs of copper oxide. (a) As-oxidized copper shot. (b) Scanning electron micrograph of copper shot after grinding

Reduction of Copper Oxide

Reduction of particulate copper oxide is generally accomplished on a stainless steel belt in a continuous belt furnace. The depth of the oxide bed is approximately 25 mm (1 in.). The typical reduction temperature ranges from 425 to 650 °C (800 to 1200 °F). Reduction occurs gradually from top to bottom of the bed. The reducing atmosphere in the furnace generally flows countercurrent to the motion of the conveyor belt.

Reducing atmospheres may include hydrogen, dissociated ammonia, water-reformed natural gas, or other endothermic or exothermic gas mixtures. Because reduction of copper oxides with hydrogen or carbon monoxide is exothermic, a careful balancing of oxide particle size, reducing gas species, and reduction temperature is necessary to optimize the reduction rate and to control the pore structure. Hydrogen diffuses readily through solid copper and is a more effective reducing agent than carbon monoxide, particularly at low temperatures. At higher temperatures, however, all reduction reactions involving either hydrogen or carbon monoxide proceed almost to completion. Free energies and heats of reaction for copper oxide reduction with hydrogen and carbon monoxide are shown in Table 2.

Table 2 Free energies heats, and partial gas pressures for copper oxide reduction with hydrogen and carbon monoxide

<Cu₂O> + (H₂) 2<Cu> + (H₂O) exothermic

2<CuO> + (H₂) <Cu₂O> + (H₂O) exothermic
$G = -24,000 - 0.01 T \ln T + 5.4 \times 10^{-3} T^2 - 3.7 \times 10^{-7} T^3 + 22.896 T$
$H_{298.1K} = -23,543$
<CuO> + (H₂) = (H₂O) + <Cu> exothermic
$H_{290K} = -31,766$
2<CuO> + (CO) <Cu₂O> + (CO₂) exothermic
$H = -33,300$

G is free energy; H is heat; values of G and H are given in calories per gram mole; P is pressure; T is the absolute temperature, degrees kelvin; and \ln is the natural logarithm (base e , where $e = 2.7182$).

(a) Total pressure is 1 atm.

Control of Powder Properties. By manipulating the reduction process, the particle porosity, pore size, and particle size distribution of the finished powder can be controlled over a wide range. As with other metal oxides, low reduction temperatures generally produce particles having fine internal porosity and correspondingly high specific surface. High reduction temperatures produce particles containing large pores and low specific surface. High reduction temperatures generally result in more interparticle sintering and more complete reduction.

Post-Reduction Procedure. The reduced copper oxide emerges from the reduction furnace as a porous cake. It is broken into smaller pieces in a jaw crusher or similar equipment, followed by fine grinding in hammer mills. The amount of work hardening is moderate, and the resulting powders have good compressibility and green strength. A scanning electron micrograph of a typical copper powder is shown in Fig. 5.

Fig. 5 Scanning electron micrograph of copper oxide reduced copper powder

Various combinations of the controlling parameters during melting, atomization, oxidation, reduction, and grinding permit the manufacture of powders with characteristics tailored to the requirements of all major applications.

The reduced and milled powder is screened and/or classified and, if necessary, blended and lubricated. These processing steps are carefully controlled to avoid losses or uncontrolled changes in characteristics such as apparent density, amount of fines, and powder flow. Some powder grades are treated with proprietary antioxidants to stabilize them against oxidation. Without this treatment, copper powders, particularly when exposed to moist air, generally tarnish, with attendant losses in green strength and other side effects. With increasing tarnish, the color of the powder changes from orange to purple to black. Simultaneously, oxygen content increases from a typical 0.1 or 0.2% to several tenths of a percent, and as much as approximately 1%. Copper powders with large specific surface areas are more sensitive to tarnishing.

Finished Powders

Finished lots of powder are subjected to a series of tests designed to ensure performance in the various applications. The single most important application for copper powder is for self-lubricating bronze bearings. In the United States, these bearings are made predominantly from elemental blends of copper and tin. Since approximately 1960, preblended and lubricated mixtures of 90% Cu and 10% Sn that have graded dimensional change characteristics during sintering have increased in use.

Table 3 lists various grades of copper powders produced by the oxide reduction process; apart from bronze bearings, applications include copper-base friction materials, electrical contacts and brushes, diamond abrasive wheels, and copper additions to iron mixes for structural parts (Ref 1). Noncompacting applications include copper fillers in plastics, catalysts, and many chemical applications. The product brochures and data sheets of the powder producers generally provide details on the characteristics and performance properties of their powders (including sintered properties), as well as recommendations for specific uses.

Table 3 Typical properties of commercial grades of copper powders produced by oxide reduction

Production of Copper Powders

David F. Berry, OMG AMERICAS; Erhard Klar, Consultant

Production of Copper Powder by Electrolysis

Production of electrolytic copper powder, as shown in Fig. 6, follows the same electrochemical principles that apply to the electrorefining of copper. The conditions of deposition, however, are changed to yield a powdery or spongy deposit, instead of the strongly adherent product desired in electrorefining. The formation of powdery deposits is favored by low copper ion concentration and high acid content in the electrolyte, as well as by high cathode current density.

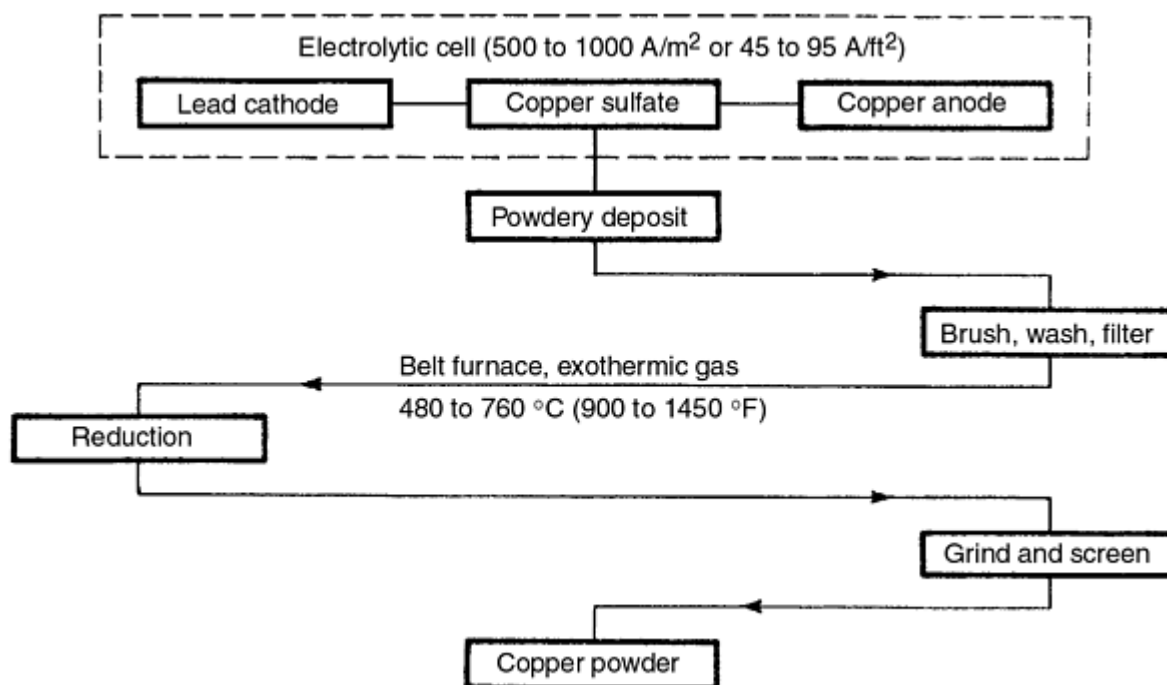

Fig. 6 Flowchart for production of electrolytic copper powder

Although these conditions yield spongy deposits, control of additional variables is necessary to produce powders that meet commercial requirements. Other factors are quantity and type of addition agent, temperature and circulation rate of the electrolyte, size and type of anode and cathode, electrode spacing, and brush-down interval. For more detailed information on electrolytic production of metal powders, see the article "Chemical and Electrolytic Methods of Powder Production" in this Volume.

Effects of Electrolyte Composition

The composition of the electrolyte is a major factor in the production of powder. Copper concentration in the electrolyte must be sufficiently low to prevent adherent deposits. In the desired range, current efficiency rises with increasing copper ion concentration, as shown in Fig. 7, with a maximum of 92% in the range of 23 to 33 g/L (3 to 4.4 oz/gal) copper. Above approximately 33 g/L (4.4 oz/gal), current efficiency decreases, and a hard deposit is produced instead of powder. Apparent density and particle size also increase with a rise in copper ion concentration.

Fig. 7 Effect of copper concentration on current efficiency and apparent density. Source: Ref 1

Acid Concentration. A high acid concentration favors the formation of powder. As shown in Fig. 8, current efficiency increases to a maximum at a concentration of 120 g/L (16 oz/gal) of sulfuric acid, then gradually falls as the acid concentration increases. Continued rise in acid concentration leads to passivity. Apparent density decreases with increasing acid concentration.

Fig. 8 Effect of acid concentration on current efficiency and apparent density. Source: Ref 1 and 14

Addition Agents. The copper sulfate/sulfuric acid electrolyte occasionally is modified to alter powder characteristics. The addition of colloidal materials, such as glue or glucose, leads to the formation of fine powder deposits, possibly because the colloid retards the evolution of hydrogen at the cathode. Table 4 indicates the effects of a number of additions to the electrolyte.

Table 4 Effect of addition agents on current efficiency and particle size

Test No.	Addition Agent	Solution strength, %	Voltage,V	Current efficiency, %	Sieve analysis, %	
					-200 mesh	-300 mesh
1	1.0	95.9	74.6	55.0
2	Boric acid	0.5	1.0	95.2	...	100
3	Glucose	0.5	1.2	85.4	...	100
4	Glycerine	0.5	1.9	94.7	...	100
5	Glue	0.5	1.5	94.5	...	100

The addition of surfactants is reported to yield a powder with controllable particle size at a current density of 215 A/m² (20 A/ft²), in contrast with the 700 to 1100 A/m² (64 to 100 A/ft²) normally used, which results in considerable reduction in power cost (Ref 2). Small quantities of copper chloride have been added to the electrolyte to increase the dendritic character of the powder particles and to increase the yield of fine powder due to the polarizing effect of the chloride ions (Ref 3). The addition of sodium sulfate reportedly reduces the cathode current density, and as the sulfate content is increased, the powder becomes finer (Ref 4). By contrast, replacement of the normal sulfuric acid electrolyte by a sulfamate electrolyte favors the formation of a coarse copper powder (Ref 5).

Effects of Operating Conditions

Alteration of operating conditions can affect process variables such as current efficiency and the formation and size of particles.

Current Density. High current density favors the formation of powder, but has only a minor effect on current efficiency. A marked decrease in particle size occurs with rising current density. For example, in an electrolyte containing 25 g/L (3.3 oz/gal) copper and 120 g/L (16 oz/gal) free sulfuric acid, increasing the current density from 600 to 1000 A/m² (55 to 90 A/ft²) raised the quantity of powder passing through a 300 mesh sieve from 20 to 96%.

Temperature. Raising the operating temperature of the cell increases the current efficiency and reduces the cell voltage. However, cell operation is difficult at temperatures higher than 60 °C (140 °F), and powders obtained at high temperatures are coarser than those produced at lower temperatures. Generally, electrolytic cells are operated at temperatures between 25 and 60 °C (77 and 140 °F).

Powder Removal. The method used to remove the powder from the cathode has a significant effect on powder characteristics. Usually the powder is removed mechanically by brushing. The brush-down interval aids in control of the particle size of the deposit and, as shown in Fig. 9, the powder becomes coarser as the interval is increased from 15 to 60 min. Figure 10 indicates that the apparent density increases as the brush-down interval is extended. Frequent brush-down also limits variations in cathode current density. In another approach to powder removal, an organic extract is used in combination with sodium lauryl sulfate to discharge the powder automatically from the cathode without brush-down (Ref 6).

Fig. 9 Effect of brush-down interval on particle size. Source Ref 1 and 14

Fig. 10 Effect of brush-down interval on apparent density. Source: Ref 1 and 14

Powder Production

The major producers of electrolytic copper powder generally follow the procedures used in electrolytic refining. However, as has been mentioned, changes in operating conditions are required to obtain a deposit of powder. Typical conditions for the production of copper powder are illustrated in Fig. 6 and can be summarized as:

Condition	Quantity
Copper	5-15 g/L (0.6-2 oz/gal)
Sulfuric acid	150-175 g/L (20-23 oz/gal)
Temperature	25-60 °C (77-140 °F)
Anode current density	430-550 A/m ² (39-50 A/ft ²)
Cathode current density	700-1100 A/m ² (64-100 A/ft ²)
Cell potential	1.0-1.5 V

Generally, the anodes are electrolytically refined copper, and the cathodes are lead alloy sheet. In a typical installation, the cathodes are 61 by 86 by 0.95 cm (24 by 34 by 0.37 in.) in dimension (Ref 7). Both anodes and cathodes are short to allow enough space at the bottom of the tank for the collection of the powder. The electrodes are arranged parallel to one another in lead-lined, rubber-lined, or plastic tanks, typically 3.4 m long by 1.1 m wide by 1.2 m high (11 ft long by 3.6 ft wide by 3.9 ft high). Each cell contains 18 cathodes spaced at 16 cm (6.4 in.) intervals and 19 anodes that are hung alternately. To ensure uniform current density and to eliminate short circuits in the cells, the electrodes are inspected frequently for prevention of excessive nodule buildup.

Typically, the electrolyte is pumped to an elevated storage tank, from which it flows by gravity into the tops of the cells and out through the bottoms. Thus, circulation is from top to bottom of the tanks, a type of circulation that yields a more homogeneous powder than that obtained by bottom-to-top circulation. The overflow returns to basement storage tanks to be recirculated.

The copper deposits on the cathode in the form of dendritic particles. To prevent short circuits between anode and cathode and heavy accumulation of powder on the cathode, both of which would decrease the cathode current density, the deposit is removed periodically by brushing.

After operating the cell for several days, the power is turned off. Most of the electrolyte is drained from the cell, leaving enough solution to cover the powder. The anodes and cathodes are washed down and removed, the remaining electrolyte is drained from the cell, and the powder is removed.

Thorough washing of the powder is essential. All traces of the electrolyte must be removed to prevent the powder from becoming oxidized. In addition, any remaining sulfate damages the heating elements if an electric furnace is used for subsequent drying and treatment of the powder. Various methods are employed to wash the powder. Although centrifuging to remove the electrolyte and wash the powder yields a clean product, the particles are compacted, and production of a low-density powder by this procedure is difficult.

In another method, the powder is transferred into a large tank, and water is added to produce a slurry that is pumped into a filter. In the filter, the powder is dewatered, washed several times, and again dewatered. Because the wet powder oxidizes readily due to its finely divided state and active surface, addition of a stabilizer is desirable. Treatment with an aqueous solution of gelatin protects the powder from oxidation in the intervals between successive operations (Ref 8). The addition of surface-active agents during washing or subsequent powder treatment also protects the powder from oxidation. Next, the powder must be subjected to a furnace operation to obtain an acceptable grade.

Furnace Operation

After thorough washing and filtering, the wet powder is ready for furnace processing. The furnace operation also alters certain properties, particularly particle size and shape, apparent density, and green strength. In a typical operation, the powder is transferred into the charge box of a mesh belt electric furnace (Ref 7). To prevent the powder from falling through the belt, a continuous sheet of high wet-strength paper is fed to the belt, and then the powder is transferred to the paper. A roller compresses the powder to improve heat transfer. As it enters the furnace, water is driven off and the paper burns, but not before the powder has sintered sufficiently to prevent it from falling through the belt.

The furnace atmosphere is produced in exothermic gas units in which natural gas and air are blended to yield an atmosphere containing 17% H₂, 12% CO, 4% CO₂, and the balance of nitrogen. The gas is refrigerated to lower the dew point to the range of -22 to -40 °C (-8 to -40 °F). The gas enters the furnace from the discharge end and, because it is refrigerated, aids in cooling the powder cake. The furnace operation dries the powder, alters the particle shape, reduces the oxides, and sinters the fines. The discharge temperature is sufficiently low to prevent reoxidation of the powder cake.

By varying the furnace temperature between 480 and 760 °C (900 and 1400 °F) and altering the time of exposure, considerable change can be made in the content of fines, apparent density, and dimensional characteristics. Upon completion of the furnace operation, the cake is broken and is ready for grinding.

Grinding and Finishing

Fine grinding is performed in high-speed, water-cooled hammer mills in which feed rate, mill speed, and screen openings under the mill can be varied to obtain the powder characteristics desired; thus, grinding is another operation in which powder properties can be changed. The powder leaving the hammer mills is fed to screens, where the oversize is separated and returned for additional grinding. The -100 mesh powder is classified in an air classifier, and the fines are transferred to the blending operation. Oversize material is returned for regrinding or is used as melting stock.

The products of the grinding and classifying operations range in apparent density from approximately 1 to 4 g/cm³. They are stored in drums to which a drying agent such as silica gel or camphor is added to prevent further oxidation. To produce high volume finished powder that meets customer specifications, powder is selected from various batches in the proper proportions and mixed in a blender. The lot is sampled before being removed from the blender, and if required, adjustments of the particle size distribution are made before the powder is packed in shipping drums. Table 5 lists the physical characteristics of several representative blends.

Table 5 Properties of typical commercial grades of electrolytic copper powders

Chemical properties			Physical properties						
Copper, %min	Hydrogen loss, % max	Acid insoluble, % max	Apparent density, g/cm ³	Sieve analysis, % Tyler

99.7	0.20	0.06	1.25-1.45	trace	10 max	90 min
99.7	0.20	0.06	0.9-1.1	trace	10 max	90 min

Process Modifications

Although most electrolytic powder is produced as previously described, other methods have been used. To obtain a very low density product, one producer employs small-size cells and handles the powder lightly in both the cell and the finishing operations. The resulting powder shape is fern-like and has an apparent density of 0.9 to 1.3 g/cm³.

Another process for the production of copper powder uses a vertical rotating titanium cathode that is partially immersed in a copper sulfate/sulfuric acid electrolyte (Ref 10). In the operation, the powder is collected continuously above the liquid level by scraping the cathode, followed by continuous dewatering, washing, and drying steps.

Properties of Electrolytic Copper Powder

The properties of electrolytic copper powder are dependent on various characteristics of the operation and, therefore, can often be controlled by altering certain process variables.

Purity of powder prepared by the electrolytic process is high, with a copper content that usually exceeds 99.5% (Table 5). A measure of the oxygen content is obtained by exposing a sample of powder to hydrogen at an elevated temperature as specified in American Society for Testing and Materials standard ASTM E 159 or Metal Powder Industries Federation standard MPIF 02, and ISO 4491/2. Generally, the hydrogen loss ranges from 0.1 to 0.5%, depending on the apparent

density and particle size distribution of the powder. Nitric acid insolubles are determined by ASTM E 194 or MPIF 08 standard procedures and generally are less than 0.05%.

Particle size distribution for copper powder is selected to meet the requirements of the application and can be varied over a wide range. As noted in Table 5, several combinations are produced, and these are only representative. For example, the -325 mesh fraction can be varied from 5 to 90%.

Apparent densities of powders are available from 1.0 to 4.0 g/cm³. Densities that are somewhat lower and higher can be produced depending on process and electrolyte conditions.

Flow rate is shown in relationship to apparent density in Fig. 11. Generally, powders with densities of less than about 1.3 g/cm³ do not flow, powders with apparent densities of 1.3 to 2.3 g/cm³ have poor flow rates, and powders with higher apparent densities flow freely. At approximately 2.2 g/cm³, which is the transition range, flow depends on the content of fine particles of the powder, because relatively fine powders have poor flowability and relatively coarse powders flow freely. The flow rates of the usual blends of electrolytic copper powder range from 25 to 40 s/50 g.

Fig. 11 Relationship between apparent density and flow rate. Source: Ref 11

Green density is a function of the compacting pressure. As shown in Fig. 12, the green density for the blend used rises from 7.2 to 8.0 g/cm³ as the compacting pressure is increased from 275 to 550 MPa (920 to 40 tsi).

Fig. 12 Effect of compacting pressure on green strength and green density. Source: Ref 9

Green strength increases with the compacting pressure, as indicated in Fig. 12. In this example, the green strength rises from less than 15 to 24 MPa (2200 to 3500 psi) as the compacting pressure is increased from 275 to 550 MPa (20 to 40 tsi).

Particle shape of electrolytic copper generally is dendritic when deposited on the cathode (Fig. 13). During subsequent operations, however, the dendrites are rounded somewhat.

Fig. 13 Electrolytic copper powder showing dendritic structure. 85×. Source: Ref 9

Compacting pressure is an important variable to consider, because the pressing and sintering conditions have a marked influence on the properties of sintered compacts. If sound compacts are to be obtained, gases from the atmosphere, from the products of reduction, or from the lubricant must escape during sintering. When the compacting pressure is too high, the flow through interconnected pores may be obstructed, and the gases cannot escape. Compacting pressures no higher than 275 MPa (20 tsi) should be used in the production of large, thick parts from electrolytic copper powder, although higher pressures can be used for thin-walled parts (Ref 12).

Dimensional changes in a typical powder blend lubricated with lithium stearate are shown in relationship to sintering time in Fig. 14. The lubricated powder blend was pressed as indicated and sintered at 1000 °C (1830 °F) in an atmosphere of dissociated ammonia atmosphere. Relatively stable dimensional changes are achieved at normal sintering times.

Fig. 14 Effect of sintering time on dimensional change. Source: Ref 9

Tensile strength and elongation of a typical powder blend are shown in Fig. 15 in relationship to compacting pressure and sintering time. The powder was lubricated with lithium stearate, pressed as indicated, and sintered at 1000 °C (1830 °F) in an atmosphere of dissociated ammonia. The graph demonstrates that good tensile properties can be obtained with short sintering times.

Fig. 15 Effect of compacting and sintering conditions on tensile properties. Source: Ref 9

Electrical conductivity that is high can be achieved. However, a high-purity powder, a characteristic of powder produced by the electrolytic process, must be used. Figure 16 shows the relationship between electrical conductivity and

sintered density; high conductivity can be achieved only in high-density compacts. Electrical conductivity can be increased by coining and resintering (Fig. 17).

Fig. 16 Effect of sintered density on electrical conductivity. Source: Ref 9

Fig. 17 Effect of coining and resintering on electrical conductivity. Source: Ref 9

Applications

Presently, electrolytic copper powder is produced in Germany, Italy, Russia, Japan, India, and Brazil where it is used in most copper powder applications (Ref 13). However, in the United States, since the early 1980s, when electrolytic copper powder production ceased, applications such as bronze bearings, copper-base friction materials and copper additions to iron mixes have, with a few exceptions, been converted to powders made by oxide reduction or water atomization. But electrolytic copper is still the powder of choice in many electrical and electronic applications, where high electrical and thermal conductivity is required. Using suitable fabricating procedures, parts can be produced with conductivities of 90%

IACS and higher. Complex parts such as armature bearing blocks, contacts for circuit breakers, shading coils for contactors, heavy-duty contacts for circuit breakers, switch gear components for use in switch boxes with capacities up to 600 A, and components for 150 and 250 A fuse blowouts are in regular production. Heat sinks for diodes used in silicon rectifiers for the alternating current system in automobiles and electrode tools for electrical discharge machining also are produced from electrolytic copper powder.

Although recently-developed oxide-reduced grades with higher purity, lower apparent density, higher green strength (see Table 3) and higher surface area (up to $0.8 \text{ m}^2/\text{g}$), have found increased usage in the manufacture of electrical brushes, electrolytic copper is still the preferred powder, having a combination of purity, high electrical conductivity, high surface area and particle morphology (dendritic shape) which allow a large volume of graphite to be accommodated while maintaining a copper matrix with high conductivity and high strength.

Electrolytic copper powder is used with various nonmetallic materials to produce friction parts, such as brake bands or clutch disks. Premixes of iron-copper or iron-copper-carbon are employed in various automotive applications--cams, sprockets, gears, piston rings for small-bore engines--and similar service.

Production of Copper Powder by Atomization

Water atomization of copper--that is, the disintegration of a molten stream of high-quality copper with high-pressure water jets--produces copper powders of compacting-grade quality. The resulting dried powder then may be subjected to an elevated-temperature treatment that further modifies its characteristics and engineering properties.

Nearly spherical powders result from the atomization of liquid copper with inert gas or air. These powders are used in copper flake production and other specialty applications. Spherically shaped copper powders have insufficient green strength for use in conventional P/M. To render them compactible, their particle shape and morphology may be changed by deformation and/or oxidation and reduction, as described in the section "Production of Copper Powder by the Reduction of Copper Oxide" in this article. Particle shapes of gas- and water-atomized copper powder are shown in Fig. 18. The following section discusses details specific to the water atomization of copper and subsequent processing. For more information, see the article "Atomization" in this Volume.

Fig. 18 Scanning electron micrographs of gas- and water-atomized copper powders. (a) Nitrogen atomized. (b) Water atomized, apparent density of 3.04 g/cm^3 . (c) Water atomized, apparent density of 4.60 g/cm^3

Commercial Practice

Liquid copper is superheated to approximately 1150 to 1200 °C (2100 to 2200 °F), utilizing flow rates of 27 kg/min (60 lb/min) or more. Generally, to produce a predominantly -100 mesh powder, water pressures of 10 to 14 MPa (1500 to 2000 psi) are used. Atomization may be conducted in an air or inert (nitrogen gas) atmosphere.

During melting of the copper, impurity content must be controlled to achieve good fluidity and high conductivity (Fig. 1). The need for oxygen control at this stage of the process depends on subsequent processing and end use of the powder. In conventional refining of copper, poling and steam-generated hydrogen keep copper oxidation under control in accordance with the equilibrium curves shown in Fig. 19. High oxygen content tends to produce a more irregular powder, and subsequent reduction of the atomized powder further improves compactibility through agglomeration and pore generation. If the powder is used in the as-atomized condition, lower oxygen contents are generally preferred, because of the detrimental effects of oxygen in many applications.

Fig. 19 Effect of partial pressures of hydrogen and steam on oxygen content of liquid copper at 1150 °C (2100 °F). $\text{Cu} + \text{H}_2 \rightleftharpoons 2\text{Cu} + \text{H}_2\text{O}$ reaction at various water vapor pressures

The apparent densities of -100 mesh gas-atomized copper powders, as a consequence of their spherical particle shape, range between 4 and 5 g/cm³. Oxygen picked up during atomization is present partly as surface oxide and partly as copper oxide throughout the bulk of a copper particle. Removal of oxygen requires reduction temperatures of approximately 700 °C (1290 °F) or higher. At these temperatures, considerable sintering occurs, which in turn requires substantial milling of the sinter cake.

During reduction, hydrogen readily diffuses through solid copper to react with oxygen and form steam. The large steam molecules, unable to diffuse through solid copper, force their way outward through grain boundaries--phenomenon known as hydrogen embrittlement of copper that manifests itself in the formation of blisters or cracks. Figure 20 illustrates the grain boundary widening of air-atomized copper particles due to this phenomenon. These defects improve both compactibility and sintering rate during liquid phase sintering of copper mixed with tin.

Fig. 20 Hydrogen-embrittled, air-atomized copper after reduction in hydrogen

Alloying Additions

Some applications of copper powders require apparent densities lower than those attainable with water atomization of pure copper. These powders can be produced by addition of small amounts, up to 0.2%, of certain elements (for example, magnesium, calcium, titanium, and lithium) to the liquid copper prior to atomization (Fig. 21 and 22). These metals are believed to decrease the surface tension of copper and/or to form thin oxide films on the particle surface during atomization. Magnesium additions are most frequently used to produce compacting-grade copper powders for applications such as bronze bearings, filters, structural parts, and additives for iron powders. These powders may have apparent densities as low as 2 g/cm^3 .

Fig. 21 Effect of additions to the molten copper on apparent density of atomized copper powder

Fig. 22 Scanning electron micrograph of water-atomized copper containing 0.5% Li

The addition of small amounts (0.1 to 0.3%) of phosphorus to the liquid copper, prior to atomization, allows the production of a powder that is very spherical and very low in oxygen. During atomization, even with air, the phosphorus oxidizes preferentially and forms protective gaseous phosphorus pentoxide (P_2O_5). Such powders have apparent densities up to approximately 5.5 g/cm^3 . Spherical copper powders with closely controlled particle size ranges are used in

applications such as thermal spray coatings, metal impregnated plastics, and heat exchangers. Irregular copper powders are used in compacting applications such as bronze mixes for self-lubricating bearings, additions to iron mixes, friction materials, electrical brushes, diamond cutting wheels, and electrical parts requiring high strength and electrical/thermal conductivity. Irregular copper powders are also used in copper brazing pastes and various chemical applications such as catalysts and in the production of copper compounds. Table 6 lists the properties of typical commercial atomized copper powders. The specific surface areas of these powders are from 0.02 m²/g for coarse spherical gas atomized powder, to 0.2 m²/g for fine water atomized powder.

Production of Copper Powders

David F. Berry, OMG AMERICAS; Erhard Klar, Consultant

Production of Copper Powder by Hydrometallurgical Processing

Hydrometallurgical methods may be used to produce a number of metal powders, including copper, cobalt, and nickel. The basic processing steps consist of preparing pregnant liquor by leaching ore or another suitable raw material, followed by the precipitation of the metal from this solution. For copper, the most important precipitation methods are cementation, reduction with hydrogen or sulfur dioxide, and electrolysis. Use of several leach-precipitation steps or the inclusion of flotation, solvent extraction, or ion exchange improves the purity of the final material.

Despite several process development efforts in the 1950s and 1960s that led to radical improvements in purity and properties of hydrometallurgically produced copper powders, commercialization attempts in the United States have failed. Causes for this failure include the increasing cost of energy, coupled with the high energy requirements of some hydrometallurgical methods and the difficulty in economically producing powders with a wide range of properties suitable for various uses.

Cement copper, like other hydrometallurgically produced copper powders, has low apparent density and high specific surface area (1 m²/g). The particles are spongy, because they are agglomerates of very small primary particles (Fig. 23). Although cement copper often has higher green strength characteristics than most other copper powders, its sintering activity, when used alone or in 90/10 bronze, is inferior because of the presence of finely divided, unreducible aluminum and silicon oxides. The primary use of cement copper is in composite friction material applications.

Fig. 23 Scanning electron micrograph of cement copper

Leaching

The leaching of copper oxide and copper sulfide ores entails partial dissolution to cupric sulfate (CuSO_4) with sulfuric acid (H_2SO_4) plus iron sulfate (FeSO_4). The presence of pyrite (FeS_2) in many ore deposits, and its reaction with water and oxygen to form iron sulfate and sulfuric acid, represents an important source of acid. In dump leaching, the pH of the leach solution is maintained between 1.5 and 3.0, partly to protect bacteria that promote and accelerate the oxidation of pyrite and sulfidic copper minerals and also to avoid hydrolysis of iron salts.

The copper content of the pregnant solutions varies from less than 1 g/L (0.15 oz/gal) to several grams per liter (ounces per gallon); for vat leaching, it can be much higher. Other leaching methods include ammonia leaching, which is used for certain copper oxide ores, and the so-called leach-precipitation-flotation method, which is applied to mixed oxide sulfide ores.

Cementation

The precipitation of a metal from its solution by the addition of another less noble metal is known as cementation. The fundamental equation for copper recovery from copper-bearing pregnant liquors on iron is:

In practice, the copper bearing solution is passed over scrap iron, such as detinned and shredded cans. Subsequent separation, washing, reduction, and pulverizing produces a copper powder that contains considerable amounts of iron and acid insolubles, such as alumina and silica. Contamination with gangue varies and depends on the nature of the pregnant liquor.

Significant reduction in iron and alumina levels is possible through the use of V-trough or inverted precipitators that allow faster precipitation rates and more efficient iron utilization. Table 7 shows chemical analyses of cement copper from different sources. Copper and iron are present, partly as oxides.

Table 7 Chemical analyses of cement copper from various location (dry basis)

Component	Composition, wt%, for location			
	A	B	C	D

Silicon dioxide	...	0.4
Lead	0.2	...
Oxygen	9.5	...

Additional Reduction Processes

Electrowinning may be used to recover copper from leaching solutions containing more than approximately 25 g/L (3.4 oz/gal) of copper (Harlan process). The electrolytic cells are equipped with insoluble lead-antimony anodes and 99% Ni cathodes. The copper powder does not adhere, but falls to the bottom of the cells. Temperature of the electrolyte is 60 °C (140 °F); cathode current density varies from 1350 to 2700 A/m² (125 to 250 A/ft²). When the copper concentration falls below 15 g/L (2 oz/gal), the electrolyte is drained and used for ore leaching. Particle size of the powder prior to furnace processing is 1 to 25 μ m, with excellent purity (>99.9%). The power requirements for electrowinning of copper are approximately ten times as large as those for electrorefining of copper with soluble anodes.

Copper may be concentrated from low-content leach solutions by solvent extraction, followed by stripping with dilute sulfuric acid into an aqueous solution and electrowinning. Carboxylic acid and hydroxylamine-based compounds have been found to be selective solvents of low water solubility, to have good stability, and to be compatible with inexpensive diluents. Direct powder precipitation with hydrogen or ammonia is an alternative to stripping the metal from the organic solvent into an aqueous solution.

Metals can be precipitated from their acid or basic solutions by reduction with hydrogen. Sulfuric acid, ammoniacal ammonium carbonate, and ammoniacal ammonium sulfate solutions have been used to produce copper powder by this method. Sulfuric acid leaching of a cement copper and hydrogen reduction of the filtered solution in an autoclave at 120 to 140 °C (250 to 280 °F) and 3 MPa (425 psi) is reported to produce a precipitate with a purity of about 100% Cu. Drying and furnace processing in a reducing atmosphere at 540 to 790 °C (1000 to 1450 °F) increases particle size, due to agglomeration of the very fine powder.

Production of Copper Alloy Powders

Thomas W. Pelletiers, II, United States Bronze Powders, Inc.; David F. Berry, OMG Americas

Introduction

COMMERCIAL COPPER ALLOY POWDERS, including brasses, bronzes, and nickel silvers, are manufactured in a similar manner. Usually, the same integrated manufacturing facilities are used to complete the melting process, atomization, final screening, and blending of a lot or batch.

The powder-producing process is similar to a foundry operation in which high-purity virgin metals are charged to a melting furnace in preweighed batches to be processed at predetermined heating rates and times. High-purity raw materials are required, because melting produces minimal refinement (only a partial transfer of contaminants from the melt to the formed slag occurs). To ensure continuity, homogeneity, and uninterrupted atomization, the molten batch of alloy is transferred to a second furnace with a greater holding capacity than the primary furnace melting rate. Induction heating is preferred for at least one furnace to ensure the constant induced metal movement required for alloy homogeneity and to ensure uniform lead dispersion in lead-bearing alloys.

Atomization is achieved by particulation of a controlled, constant-flowing, molten stream emitted from the secondary furnace by medium-pressure dry air. A typical melting and atomizing sequence is shown in Fig. 1. Subsequent reduction of oxides is not required for standard P/M grades.

Fig. 1 Flowchart for copper alloy powder air atomization. SQC, statistical quality control; SPC, statistical process control

Air-cooled, atomized powder is collected and passed over a primary control screen (sieve) to remove oversize particles. Usually, these are remelted concurrently during the processing of each alloy. Finally, the screened alloy powder may be blended with dry organic lubricants, such as lithium and zinc stearate, for use in the manufacture of P/M structural components.

Adjustment of powder properties (particle size distribution, apparent density, green strength, etc.) of each alloy is accomplished by controlled manipulation of the atomizing process conditions (e.g., atomizing air flow rate, molten metal temperature, nozzle configuration, etc.). Powder properties are maintained by periodically recording the atomizing parameters and by evaluating the properties of representative samples from the in-process atomized product.

A variety of copper-base alloys can be manufactured by the atomizing process; however, commercial P/M applications normally are confined to a rather narrow range of specific, single-phase () compositions.

Brasses

Brasses comprise the major portion of copper-base alloy powders used for parts fabrication, in comparison with prealloyed bronze and nickel silver materials. Typical copper-zinc brass powders contain zinc contents ranging from 10 to 30%. Lead may be added in small amounts (1 to 2%) to improve machinability of the sintered compact. A photomicrograph of an 80%Cu-18%Zn-2%Pb alloy powder is shown in Fig. 2. The melting temperatures of these alloys range from 1045 °C (1910 °F) for 90%Cu-10%Zn to 960 °C (1760 °F) for 70%Cu-30%Zn. As zinc content increases, melting temperature is lowered.

Fig. 2 Scanning electron micrograph of prealloyed, air-atomized brass (80%Cu-18%Zn-2%Pb). 165×

Additional superheat, or the temperature in excess of the alloy melting temperature, depends on heat losses within the manufacturing system and the physical property requirements of the atomized powders. Typical physical properties of brass alloy compositions are given in Table 1.

Table 1 Physical properties of typical brass, bronze, and nickel silver alloy compositions

Property	Brass ^(a)	Bronze ^(a)	Nickel Silver ^{(a)(b)}
Sieve analysis, %			
+100 mesh	2.0 max	2.0 max	2.0 max
-100 + 200	15-35	15-35	15-35
-200 + 325	15-35	15-35	15-35
-325	60 max	60 max	60 max
Physical properties			
Apparent density	3.0-3.2	3.3-3.5	3.0-3.2
Flow rate, s/50 g	24-26
Mechanical properties			
Compressibility ^(c) at 414 MPa (300 tsi), g/cm ³	7.6	7.4	7.6
Green strength ^(c) at 414 MPa (300 tsi), MPa (psi)	10-12 (1500-1700)	10-12 (1500-1700)	9.6-11 (1400-1600)

- (a) Nominal mesh sizes; brass, -60 mesh; bronze, -60 mesh; nickel silver, -100 mesh.
- (b) Contains no lead.

Bronzes

Prealloyed atomized bronze compositions are not used extensively as base powders for compacted parts fabrication because of their nodular particle form and high apparent density, both of which contribute to poor compacted green strength. Common prealloyed compositions are 90%Cu-10%Sn and 85%Cu-15%Sn, prepared in the same manner as brass powder, except that high-purity elemental copper and tin are used. A scanning electron micrograph of an 89%Cu-9%Sn-2%Zn alloy powder is shown in Fig. 3. Typical physical properties of a bronze alloy composition are given in Table 1.

Fig. 3 Scanning electron micrograph of prealloyed, air-atomized bronze (89%Cu-9%Sn-2%Zn). 165×

Prealloyed bronze powders are also made commercially by water atomizing. Application is more extensive in Europe, where 90/10 prealloyed bronze powders are incorporated in bronze premixes for bearing manufacture. Low green strength due to high apparent density (3.2 to 3.6 g/cm^3) is overcome by incorporating lower apparent density copper powders and choice of lubricants that have a less deleterious effect on green strength. Physical properties are similar to air-atomized powders, but particle morphology is different (Fig. 4). Powders contain 0.1 to 0.2% P to aid sintering.

Fig. 4 Scanning electron micrograph of a typical prealloyed water-atomized bronze powder (90%Cu-10%Sn); apparent density 3.4 g/cm^3 . 200×

Spherical 89/11 bronze powders are used to make filters. These are made by horizontal air atomizing and dry collection. The spherical shape is achieved by addition of small amounts of phosphorus, 0.2 to 0.45% (in the form of a Cu/15% P alloy) to the molten bronze prior to atomizing. During air atomizing, surface oxidation of atomized molten particles of bronze and brass, which cause them to solidify in an irregular shape (see Fig. 3) is prevented. The oxygen in the air preferentially reacts with phosphorus to form phosphorus pentoxide (P_2O_5), which is volatile at atomizing temperatures.

The spherical powders are screened to produce a number of grades, each with a narrow particle size range. An assortment of filters made from bronze powders and properties of four grades of filters are shown in Fig. 5 and Table 2.

Table 2 Properties of four grades of filter materials produced by loose powder sintering spherical powders

Particle size of spherical powder particles		Tensile strength		Recommended minimum filter thickness		Largest dimensions of particles retained, μm	Viscous permeability coefficient, m^2
Mesh range	Range in μm	MPa	ksi	mm	in.		
20-30	850-600	20-22	2.9-3.2	3.2	0.125	50-250	2.5×10^{-4}
30-40	600-425	25-28	3.6-4.1	2.4	0.095	25-50	1×10^{-4}
40-60	425-250	33-35	4.8-5.1	1.6	0.063	12-25	2.7×10^{-5}
80-120	180-125	33-35	4.8-5.1	1.6	0.063	2.5-12	9×10^{-6}

Microbearings. A more recent development has been prealloyed bronze powders for microbearings. These are very small bearings, often weighing less than 1 g, used in electronic equipment such as computers, audiocassette players, and videocassette recorders. Most powders used in this application are made by diffusion alloying tin into copper powder to produce a substantially alloyed powder with particles of uniform composition and a particle shape that gives high green strength (apparent density of 2.3 to 2.7 g/cm^3). As previously stated, water-atomized bronze powders have relatively high apparent density (3.2 to 3.6 g/cm^3) and are usually limited to application in high-density structural parts. Figure 6 shows the particle morphology of a typical diffusion-alloyed bronze powder.

Fig. 6 Scanning electron micrograph of a typical diffusion-alloyed bronze powder (90%Cu-10%Sn); apparent

density 2.6 g/cm³. 200×

Nickel Silvers

Only one nickel-silver-base alloy composition, 65%Cu-18%Ni-17%Zn, is commonly used in the P/M industry. This alloy can be modified by the addition of lead to improve machinability. Foundry practices are similar to those employed for brasses, except the melting temperature is in excess of 1093 °C (2000 °F). A micrograph of a 63%Cu-18%Ni-17%Zn-2%Pb alloy powder is shown in Fig. 7. Typical physical properties of a nickel silver alloy composition are given in Table 1.

Production of Tin Powders

William J. Ullrich, ACuPowder International, LLC

Introduction

TIN POWDERS are used extensively in the production of porous, self-lubricating bronze bearings and as constituents in soldering and brazing pastes and powders. Low-melting-point tin powders normally are produced by air atomization, although other methods of production such as chemical precipitation and electrodeposition have been used (Ref. 1). Tin powders also are used in powder metallurgy (P/M) structural parts, friction disks, clutches, brake linings, metal graphite brushes, diamond abrasive grinding wheels, bronze filters, peen plating, plasma arc spraying, chemical formulations, additives for rubber and plastics, chemical manufacturing, smokeless powder for pyrotechnics, and tin flake.

Melting

High-purity pig tin is melted in a gas-fired or electrically heated crucible (cast iron, clay, graphite, or ceramic). Melt temperature is controlled to maintain the desired degree of superheat above the low melting point of tin (232 °C, or 449 °F).

Production of Tin Powders

William J. Ullrich, ACuPowder International, LLC

Atomization

Atomization results in a fine powder whose average particle size can be regulated over a wide range. Resultant powders are of high purity. Excessive oxidation, characteristic of other atomized products, does not occur because of the rapid chilling effect of the expanding gases released through the nozzle. Thus, the oxygen content of atomized tin is normally below 0.2%. The thin film of oxide produced during atomization with steam or air is sufficient to inhibit further oxidation of the particles.

The molten tin can be atomized vertically (up or down) or horizontally, depending on the nozzle direction, to produce a powder (Fig. 1). There are two atomization techniques: annular nozzle and cross-jet atomization. In an annular nozzle, the gas stream aspirates liquid tin into the nozzle, where it is disintegrated into tiny droplets by the high-velocity gas stream. In cross-jet atomization, the gas is at right angles to the molten tin stream. This method usually produces coarser particles than annular nozzles.

Fig. 1 Schematic of apparatus for atomizing tin powder

To atomize uniformly fine tin powders, temperature, stream diameter, and flow rate of the molten tin and temperature, pressure, velocity, and angle of impingement of the atomizing gas must be well controlled. Pressures commonly employed to atomize tin powder range from 345 to 1725 kPa (50 to 250 psi). Generally, finer powders require the higher pressure; however, the exact pressure is related to the nozzle design used.

Compressed air is usually used as an atomizing medium. It is frequently preheated in a gas-fired heat exchanger to prevent solidification of tin within or around the orifice caused by the chilling effect of expanding air as it is released through the nozzle. Nozzles are designed to facilitate the atomization of several different particle size ranges, usually by changing orifice diameter and air pressure.

A blower (fan) at the end of the system pulls the atomized tin powder from the atomization chamber into a cyclone, where it is collected. The finest particles, which have not settled in the cyclone, are then retained in the cyclone filters. The tin powder collected in the cyclone is sieved to remove the oversized particles, most commonly +100, +200, or +325 mesh.

A uniform mixture of tin powder of the desired lot size is produced by tumbling in a blender. A sample of the blended tin is then analyzed for physical and chemical properties. The tin powder is packed in steel or waterproof fiber containers weighing up to 320 kg (700 lb).

Production of Aluminum and Aluminum-Alloy Powder

A. Ünal, D.D. Leon, T.B. Gurganus, and G.J. Hildeman, Aluminum Company of America

Introduction

ALUMINUM POWDERS and ALUMINUM alloys are produced almost exclusively by gas atomization. For most applications, the atomizing gas is compressed air; however, in some special cases, inert gases (helium, nitrogen, and argon) are used. Between 25 and 30 countries in the world are known to have production facilities for aluminum powder at an estimated total capacity of 200,000 tons per year (Ref 1). A large portion of this capacity is in North America where annual shipments are about 40,000 tons (Ref 2). Atomized aluminum powders are used in a variety of applications that include pyrotechnics, explosives, rocket fuel, thermite welding, aluminothermic reduction, chemical processes (as catalyst or reagent), additives for lightweight concrete, pharmaceuticals, and pigments for paints and printing inks. With few exceptions, the demand is for unalloyed powder of various standards of purity. Aluminum alloy P/M, historically a small percentage (about 1%) of the total powder market, has been enjoying a revival in recent years in automotive applications because of the need to reduce weight, lower emissions, and boost fuel economy. Viable P/M applications include engine cam caps and air conditioning compressor parts. Powder metallurgy offers competition to wrought aluminum castings and stampings because of its net shape advantage.

Production of Aluminum and Aluminum-Alloy Powder

A. Ünal, D.D. Leon, T.B. Gurganus, and G.J. Hildeman, Aluminum Company of America

Historical Background

Aluminum powder was first used commercially as flakelike pigment products called aluminum bronze powder in the United States around 1900. It was made from aluminum sheet by the Bessemer dry stamping process developed fifty years earlier for the manufacture of gold powders. Stamping mills were both inefficient and dangerous to operate, because, unlike gold powders, aluminum powder forms an explosive mixture with air over a wide range of metal-to-air ratios (Ref 3). Several fatal fires and explosions marred the early days of the aluminum powder industry.

Two major breakthroughs developed by Hall (Ref 4) occurred in aluminum powder production in the late 1920s. First, the development of safer ball mill production processes that are still employed today for milling powders into flakes. Second, the introduction of the atomization process, which allowed the manufacture of the forerunners of today's atomized powders. Atomized aluminum powder was used initially only as raw material to produce aluminum flake pigments by ball milling. After World War II and the development of aluminized high explosives, a major market for atomized aluminum was created. The application of atomized powders broadened in postwar years from military explosives to commercial markets listed above.

To meet the individual needs of each of these markets, manufacturers now produce many grades of aluminum powders in several different general categories: granules, regular and coated atomized powders, spherical powders, high-purity powders, alloy powders, blended powders, and dedusted atomized powders. All are produced by the same basic gas atomization technique, but starting materials may differ and, as with flake powders, further processing may be required. Powders atomized in inert gas (nitrogen, argon, and helium), which have a spherical shape, are preferred for some applications. Water atomization of aluminum is not practiced because it is dangerous, due to the creation of hydrogen and the potential presence of rust in the equipment. The latter can lead to explosions through thermite reaction with the dry powder. Some manufacturers still use the dry stamping process for converting foil scrap into coarse particulate (granules), although it is now a very small percentage.

Gas Atomization

There are many methods that have been used to produce aluminum and aluminum alloy powders including gas and centrifugal atomization, ultrasonic or pulsed atomization, melt spinning with attrition, and mechanically alloying. Gas atomization is used for several applications.

In gas atomization, a high-velocity gas jet disintegrates molten aluminum into droplets that solidify to form the powder. In the Alcoa process (Fig. 1), the material flow during atomization is vertically upward (also known as "updraught"). Molten metal of the appropriate composition is supplied from a holding or melting furnace at the required temperature to the atomizing bay. The liquid is drawn from the bay through a liquid delivery tube into the atomizing nozzle. This is achieved by the aspirating effect (suction) caused at the nozzle end of the delivery tube by the flow of the high-pressure atomizing gas in the nozzle. When the liquid metal meets the high-velocity gas, it is broken up into droplets and sprayed as a jet. The droplets are quenched by the gaseous atmosphere in the chamber to solidify as powder particles. These particles, together with a substantial volume of cooling air, are then drawn through a chiller chamber into the collection system consisting of two sets of cyclones. After the cyclones, the powder is transported in an atmosphere of inert gas to the screens and pack-outs where they are packed under inert gas into drums and bins or onto railroad cars or trucks.

Fig. 1 Schematic of the Alcoa process for atomizing aluminum powder. Entire operation is under computer control. Powder is packed in drums or bins or is loaded for bulk shipment in trucks or railroad cars.

Because aluminum powder forms an explosive mixture with air over a wide range of metal-to-air ratios, aluminum powder plants have explosion hazards associated with them. The Alcoa process (Fig. 1) incorporates several safety features. The bottom of the chiller chamber is closed rather than open to prevent ingress of combustible dust and foreign matter into the atomizing zone. Cooling air entering the chiller chamber is filtered in order to remove foreign matter and ignition sources, such as rust particles. The chiller chamber walls are reinforced. Explosion vents are located in the chiller chamber, along the exhaust duct, and in other critical locations, such as the lids of the cyclone abatement chambers. These

vents open up and minimize pressure buildup in the event of an explosion. To reduce explosion hazards between the atomizing nozzle and the cyclones, the airborne concentration of aluminum powder is kept to a level below which forms an explosive mixture (lower explosive limit, LEL). Airflow in the system is created by means of an eductor, so that powder does not have to travel through a rotating fan, which eliminates a significant static electricity ignition source. The whole plant is built in stainless steel and fully grounded to eliminate the danger of sparking and static buildup. The transport of powder after the cyclones is done in an atmosphere of inert gas, as noted above, to substantially reduce the explosion hazard. A certain level of oxygen is maintained in the inert gas atmosphere to ensure that the powder does not become pyrophoric.

Workers are removed entirely from areas containing the greatest hazards by substitution of computerized controls, remote TV surveillance, and automated operations. Conductive shoes are provided to workers in powder handling areas. Good housekeeping and training of operators are essential elements of safe operation in an aluminum powder plant. Regular audits of plant equipment and operating practices are carried out to ensure compliance. Areas of improvement identified in such audits and by risk assessment procedures are implemented on a timely basis.

The industry has recognized the hazards of aluminum powder. Manufacturers and users of aluminum powders cooperate in reporting and analyzing incidents through the auspices of The Aluminum Association. The Association holds safety workshops and supports research relating to safety funded by the members.

Control of particulate emissions in industrial plants is an important criterion. In the United States, these requirements vary from state to state. Pennsylvania has one of the strictest specifications limiting particulate emissions rate to 0.09 g/Nm^3 (0.04 grains/ft^3) of dry process air for aluminum powder plants. To meet these stringent requirements, manufacturers of aluminum powders often collect the powder in two stages of cycloning followed by a baghouse. Opacity of the plume from the plant is monitored and recorded. The upper limit for opacity is often specified at 10% max. These two specifications of emissions do not in general correspond to each other for aluminum powder plants (Fig. 2). This may be attributed to fine particles ($<1 \mu\text{m}$) causing a disproportionately high obscuration of the sunlight in the plume than coarser particles would cause.

Fig. 2 Dust concentration and mean opacity readings measured in a pilot aluminum atomizer

Vertically upward aspirating processes, such as that operated by Alcoa, permit better control of the metal delivery rate to the nozzle and thus the production of the widest range of powder grades: fine, medium, and coarse. Aluminum powder

atomizing can be accomplished also by directing the molten metal stream either horizontally or vertically downward. Systems that utilize metal-head pressure to induce molten metal flow through the nozzle often atomize either vertically downward or horizontally. Aspirating systems, on the other hand, usually prefer to atomize horizontally or vertically upward. Multiple nozzles are often used in commercial operation to achieve the required rates of production.

Atomizing Nozzle Technology. The first nozzle used for atomizing aluminum powders was invented by Hall in the late 1920s (Ref 4). In the Hall design, the atomizing gas (compressed air) is delivered through an annular orifice around the nozzle at a converging angle, as shown in Fig. 3. The gas flow creates a suction (aspiration) effect at the tip of the nozzle that is utilized to draw the molten metal into the nozzle. The amount of gas delivered by the nozzle is controlled by the size of the air gap, and pressure and temperature of the gas. Rate of metal flow and resultant powder particle size are influenced by the aspirating force, the nozzle metal orifice diameter, and the vertical distance between the nozzle and the molten metal level.

Fig. 3 Aspirating nozzle design developed by E.J. Hall in 1920s. Source: Ref 4

The Hall nozzle is a good example of the general class of confined nozzles, or close-coupled nozzles. This nozzle design aims to contact the liquid metal with the gas at or close to the gas jet exit plane, thus making use of the high jet velocities at that point. It leads to efficient breakup of the liquid, resulting in finer powders, and is the preferred method for aluminum and rapidly solidified fine powders of other metals. It can be operated vertically upwards or downwards or in the horizontal position. Careful design of the nozzle is required, however, to avoid the quenching of the metal by the gas jet, which can lead to premature solidification at the nozzle tip.

In the operation of the confined design nozzles, it has been observed that the molten metal presents itself as a thin film to the gas jet. This filming effect, which is beneficial for efficient breakup of the liquid, occurs from the gas flow pattern and toroidal recirculation vortexes above the nozzle (Fig. 4). The vortexes in this flow pattern cause the liquid to spread radially on the top of the delivery tube into a thin film. This is the preferred operating regime for producing fine powders. When the metal flow rate is too high, the filming effect is partially lost, and some of the metal is pulled into the low-velocity wake and does not film effectively (Ref 5, 6). Such operation leads to coarser powders and to the formation of undesirable flakes in the powder.

Fig. 4 Fluid flow pattern at the tip of a confined nozzle during atomization

The toroidal recirculation vortices of confined nozzles are caused by fluid entrainment on the inner boundaries of the annular jet (Ref 7). When a jet exits from an annular nozzle, a mixing zone is formed due to the shearing action of the jet on the surrounding fluid. As there is no supply of fluid in the central region to satisfy the entrainment requirements of the inside boundaries, the jet is forced to draw this fluid from the mainstream jet itself. By forming recirculation vortices, the jet is able to feed itself with its own fluid and hence satisfy entrainment requirements. Associated with the vortices is a zone of subatmospheric pressure at the tip of the nozzle, and the resulting radial pressure forces draw in the annular jet toward the axis. As the converging streamlines approach the axis, a region of stagnation is set up at some distance downstream from the axis. The high pressure at this point redirects the flow away from the axis, until finally the combined jet expands in the same way as a single round jet. Similar recirculation flows can also form on the outside due to entrainment on the outer boundary if the amount of fluid available is restricted, as in the case of a jet being blown into a closed container. It is important to avoid recirculating flows in the vicinity of the atomizing jets that can lead to multiple collisions between the spray and the powder particles and result in excessive satelliting.

The low pressure (suction, aspiration) created at the nozzle tip is a useful feature of the confined design. It is employed to draw the liquid metal into the nozzle from the crucible in updraught operation, as mentioned above. Additionally, the presence of suction at the point of contact between the gas and the liquid avoids the potentially hazardous blowback effects observed in free fall nozzles for certain jet geometries. The level of suction created by a nozzle is found to be extremely sensitive to nozzle geometry, atomizing gas, and operating pressure (Ref 8).

Nozzle designs used in the aluminum powder industry are proprietary and information on their performance is not available. Information has become available in recent years on several different confined nozzle designs developed for use with molten metals, some of which have been applied to aluminum. It is instructive to review some of the more important designs.

Ultrasonic gas atomization (USGA) has been promoted by Grant (Ref 9). This nozzle invented by Kohlswa Jernwerk of Sweden and patented in the United States in 1961 uses a modification of the original design with a multitude of discrete holes for gas delivery. Each gas jet contains a pair of resonating (Hartmann) cavities in its path, as indicated in Fig. 5. The original patent claims that ultrasonic vibrations are created in the gas jet that lead to the production of finer powders. Published reports of experimental work with metal powders have not supported that claim. Further, the modified design has been shown to lead to unnecessarily high frictional losses (Ref 12).

Fig. 5 Schematic of USGA nozzle design. Source: Ref 10

NIST Design. The nozzle developed at NIST is similar to the USGA design, but it does not contain the Hartmann cavities (Ref 13, 14). The gas jets are inclined to metal delivery axis at an included angle of 45° (Fig. 6). With such designs, too, under certain conditions, positive pressure rather than suction is created at the tip of the nozzle. The selection of operating conditions then becomes crucial. Recent work by Mates (Ref 6, 16) has shown that filming of the molten metal takes place also in this design. It is, however, sensitive to the operating parameters and is not always complete, and metal can exit the nozzle in the form of ligaments and sheet (Fig. 6) as proposed by NIST workers.

Fig. 6 Particle formation mechanism proposed for the NIST nozzle that operates vertically downwards. Source: Ref 15

Nanoval Nozzle Design. Nanoval has recently introduced a nozzle design (Fig. 7) in which the molten metal is delivered to the throat of a converging-diverging nozzle in the form of a thin stream (Ref 10). It is thus conceptually similar to the free fall design; but because the metal stream is always kept very thin and it is delivered directly to the throat of the nozzle, this design is capable of producing very fine powders. Nanoval has produced stainless steel powders of 6 μm median diameter by this method in pilot quantities. No filming is likely to occur in this design, because it is necessarily restricted to very low rates of production and best suited possibly for precious metals. The manufacturer also claims substantial gas savings.

Fig. 7 Schematic of Nanoval nozzle design. Source: Ref 11

Free fall nozzle designs (Fig. 8) are also known to be used in the aluminum powder industry. In this design, the liquid metal issues in the form of a stream from a tundish and falls 50 to 200 mm by gravity. Then it is atomized by the gas directed at a point, either by means of discrete jets or an annular nozzle concentric with the metal stream. This method is easy to operate but highly inefficient and is not suitable for making fine powders.

Fig. 8 Atomization design characteristics: α , angle formed by free falling molten metal and impinging gas; A , distance between molten metal and gas nozzle

Formation of Powder Particles. Recent studies on the operation of confined nozzles have shown that the liquid film obtained in these nozzles breaks up in two stages to form the powder particles. The first stage (primary breakup) occurs at the point of first contact between the liquid film and the gas jet along the edge of the delivery (Fig. 4). Liquid droplets formed at this stage can have up to 500 μm diameter under normal operating conditions with aluminum. These droplets undergo further disintegration in flight (secondary breakup), as is evident from the absence of such large particles in the resulting powders. Similar stages are described for the NIST design by Ridder et al. (Ref 13) for the breakup ligaments and the droplets formed.

Primary breakup is not well understood, but it is known from experiments that unsuitable nozzle designs or operating conditions can lead to incomplete breakup and/or formation of filaments at the nozzle tip, which may eventually become flakes in the powder. It is accepted that proper completion of the primary breakup stage is essential for the production of fine powders. The filming mechanism facilitates the breakup. Also, swirl in the atomizing gas is likely to be helpful. Indeed, swirl is one of the important features of the nozzle design patented by Hall in 1928 for making metal powders. Most interestingly, Miller (Ref 11) has recently introduced nonaxisymmetric metal delivery tubes and has found them to be beneficial in the atomization of superalloys. He reported that they lead to the formation of multiple plumes at the tip of the nozzle, which would break the ligaments into smaller parts and thus enhance the efficiency of the primary breakup stage. Miller also notes that with asymmetric nozzles, the pinching of the plume is much reduced. He suggests that the resulting reduction in the level of droplet collision and coalescence would also contribute to the improved efficiency observed. It is important to note that the largest benefits were observed at the higher range of atomization rates (lower range of the gas/metal ratios) that correspond to coarse powders.

Secondary Breakup. The breakup of single droplets in a flowing gas has been studied using materials that are liquid at room temperature, such as water, oils, and glycerin. Lane (Ref 15), one of the earliest to publish work in the field, identified two main mechanisms of breakup as "bag" mechanism and "stripping" mechanism, shown in Fig. 9 applicable at low and high Weber numbers (W), respectively.

Fig. 9 Secondary breakup mechanisms proposed by Lane. Source: Ref 17

Experimental evidence for the occurrence of secondary breakup in metal powder production can be obtained from studies of the atomizing spray at very low metal flow rates. At such low rates, individual droplets become visible (Fig. 10) and show "tails" in the direction of the gas flow as suggested by Lane. Weber numbers obtained in metal atomization are generally very high, and Ünal (Ref 7) concluded on that basis that breakup occurs by stripping. In that mode, the droplet first deforms in such a way as to present a convex surface to the gas flow. The edges of this saucer-shaped droplet are then drawn out into a thin sheet and torn into ligaments, which are later broken into smaller droplets. These particles (daughter particles) form the fine size range of the powder. As droplets get progressively smaller through disintegration, a point comes at which surface tension forces, which are inversely proportional to diameter ($4\pi/d$), become sufficiently great to resist the aerodynamic drag forces responsible for the breakup. At this point, secondary breakup ceases, and the

droplets solidify to form the coarse range of powder particles. From earlier studies of the breakup of single droplets, Ünal (Ref 7) deduced that this occurs when the Weber number (W) takes on a value of 13. That is, for stable particles:

$$W = \rho_g u^2 d / \sigma = 13$$

This equation can be used to calculate the size (d) of the stable droplets:

$$d = 13 \sigma / \rho_g u^2$$

Fig. 10 Metal film left in the tip of the nozzle in the rundown mode

A range of stable particle sizes is obtained because the gas decelerates and the particles accelerate as a function of distance from the nozzle. The lower limit for stable sizes is that obtained at the tip when the relative velocity is a maximum. This has been estimated at $30 \mu\text{m}$ for aluminum and for the common atomizing gases, such as nitrogen, argon, and helium. The largest size found in the powder can be used to estimate the relative velocity at which secondary disintegration is complete. These estimates have indicated that the process is likely to be completed while the gas flow is still supersonic in a well designed nozzle.

It is important to appreciate that the presence of stable particles in the final product can apply only to such liquids as molten metals, which have high surface tension and low viscosity. For other liquids with low surface tension, the stable sizes may be so small as to be comparable to that of the daughter particles, in which case they would be indistinguishable. Ünal et al. (Ref 19) found that to be true with wax powders atomized in air. These powders have a tighter size distribution represented by the Rosin-Ramler law as opposed to the log-normal law that generally applies to atomized metal powders.

Production of Aluminum and Aluminum-Alloy Powder

A. Ünal, D.D. Leon, T.B. Gurganus, and G.J. Hildeman, Aluminum Company of America

Particle Size Distribution

When various mechanisms operate to produce a powder, these occurrences should appear as peaks in the frequency distribution plots. Nitrogen and argon atomized powders in Fig. 11 show three areas of peaks. The first, at $5\ \mu\text{m}$, is considered to represent the daughter particles (Ref 21, 22). The third peak belongs to the stable sizes, which range from $30\ \mu\text{m}$ to $100\ \mu\text{m}$ and greater. The intermediate peaks are taken to indicate considerable overlapping between the daughter particles of large droplets breaking up at lower relative velocity and stable sizes of initially small drops shattering at high relative velocity. The peaks are not so well defined in the case of helium atomized powder, showing complete merging.

Fig. 11 Frequency distribution for AA 2014 powders made using helium, argon, and nitrogen. Source: Ref 20

The distribution of particle sizes in atomized metal powders is often found to comply approximately with the log-normal law (Ref 21, 22). The two mechanisms for the production of fine and coarse droplets described above are not compatible with this law, which is strictly unimodal. The wide range of sizes covered is its main advantage in representing satisfactorily the size distribution of gas-atomized metal powders.

Several mean diameters are used to describe the size of a powder. The most common is the mass median diameter, d_m , i.e., the 50% point on the cumulative weight versus particle size graph. Two other useful mean diameters are the Sauter mean diameter d_{vs} and the volume mean diameter d_{vm} , defined by:

$$d_{vs} = \frac{\sum x^3 dN}{\sum x^2 dN} = \frac{100}{(\sum d\Phi/x)}$$

$$d_{vm} = \frac{\sum x^4 dN}{\sum x^3 dN} = \frac{\sum xd\Phi}{100}$$

where $1x$ = mean diameter in a size band, dN = number of particles in size band, $d\Phi$ = weight percent in size band. Sauter mean diameter is the diameter of a sphere with the same surface area per unit volume as the powder and is sensitive to changes in the fine particle range of the powder. Volume mean diameter, on the other hand, is a moment mean, sensitive to changes in the coarse particle range. Both these two diameters are easily calculated from the sizing data and are routinely reported in sizing reports obtained in light scattering type instruments.

A single mean diameter is not sufficient to describe a powder; information is also required on the spread of sizes about the mean. This is measured by the geometric standard deviation of the log normal distribution and is calculated:

$$\sigma_g = (d_{84.1}/d_{15.9})^{1/2} = (d_{84.1}/d_{50}) = (d_{50}/d_{15.9})$$

The σ_g values for gas-atomized aluminum powders tend to increase as the mean particle size increases indicating that the distribution becomes less tight for coarse powders. The typical range of σ_g is from 1.8 to 2.5 (Fig. 12).

Fig. 12 Variation of geometric standard deviation with median particle size for as-atomized particles

In the case of log-normal distribution of sizes, all mean diameters are related to each other. Hence, if one diameter and the value of σ_g are known, all other mean diameters can be calculated. The relationship between the two common mean diameters, d_{vs} and d_{vm} , and the mass median diameter, d_m , is given by the following equations:

$$\begin{aligned} \ln d_{vm} &= \ln d_m + 1/2 \ln^2 \sigma_g \\ \ln d_{vs} &= \ln d_m - 1/2 \ln^2 \sigma_g \\ d_m^2 &= d_{vs} d_{vm} \end{aligned}$$

These relationships are useful in checking consistency of the data and the applicability of the log-normal law to any size distribution obtained. Figure 12 can be used for quick estimates of the σ_g from the ratio of these mean diameters.

Control of Particle Size. By modifying process parameters and screen sizes, the particle size distribution of atomized powders can be adjusted to produce a wide range of products from aluminum granules (typically +200 mesh) to fine atomized powders (up to 99%, -325 mesh). Figure 13 shows particle size distribution curves for typical coarse, medium, and fine grades of atomized powders. Besides the wide range of grades available from direct atomizing, others are possible from blending screen fractions and air classification.

Fig. 13 Particle size distribution measured by Microtrac in some Alcoa powder grades (grade 130/2 is by sonic sieve method)

Important process parameters in atomizing pure metals include nozzle configuration, nature, pressure, and temperature of the atomizing gas and delivery rate, and temperature of the molten metal. For alloy powders, nature and content of the alloying elements also need to be taken into account. Special precautions are often needed in atomizing alloys that contain alloying elements that evaporate or oxidize readily.

The geometry of a nozzle controls the flow of the atomizing gas and is therefore of the utmost importance in any atomization process. Information on the influence of nozzle design is scanty and empirical, and it mostly originates from patent literature. A recent study on a confined design nozzle has amply illustrated the influence of nozzle configuration (Ref 5) on the particle size of the as-atomized aluminum powders. Some results from that study are shown in Fig. 14. To eliminate variation due to differences in the amount of gas delivered by different designs, the results were replotted against the ratio of gas used per unit metal atomized. It is noted that a good design can produce substantially finer powders for the same amount of gas used. In subsequent gas flow studies, good nozzle designs have been found to maintain the supersonic nature of the jet farther in the jet plume than poorer designs, thus allowing the secondary breakup process to take place in a high-velocity gas jet.

Fig. 14 Variation of mass median diameter for aluminum powders with the ratio of metal/gas

The influence of nature and pressure of the atomizing gas on particle size of the as-atomized powder are well established. Helium produces much finer powders than those produced by nitrogen and argon under similar conditions using the same nozzle (Fig. 15). Comparison on the basis of volume of gas used per unit weight of powder produced also shows helium to be superior to argon. Helium atomized powders as fine as 13.5 μm median diameter have been obtained using unheated gas. Under similar operating conditions, nitrogen atomized powders were 23 μm and argon atomized powders were 25 μm . This difference is attributed to the higher gas velocities attained in helium in supersonic flow. Similar benefits are expected from higher gas temperatures due to increased velocities. Further, heated gases will help reduce the danger of the premature freezing of the metal at the nozzle tip. With respect to gas pressure, it is known that a given nozzle, when all other parameters are constant, will produce finer powders as the gas pressure is increased. However, as the gas flow rate also increases linearly with pressure, the observed effect is similar to a more favorable gas/metal flow ratio, as well as that of increased pressure. When the results are compared on a gas/metal flow ratio basis, higher operating pressures are still beneficial.

Fig. 15 Comparison of argon and helium gases on the basis of gas volume used per unit weight of powder produced

During manufacture, particle size control in the as-atomized state is achieved by the selection of the rate of atomization (metal delivery rate). For any given nozzle configuration and operating parameters, the rates have to be slowed down in order to make finer powders. The median diameter is found to be approximately proportional to the square root of the rate of atomization. This may be more generally expressed as a function of the metal/gas flow rate ratio (Fig. 14). Superheat in the molten metal was found to have only a small effect on the powder size providing that there was sufficient heat in the liquid to prevent premature solidification. This is reasonable, as any change would come about primarily through changes in such properties of liquid metal as surface tension, density, and viscosity. These properties are only mildly dependent on temperature.

As metal flowrate is increased and the powder becomes coarser for any given atomizing conditions, in general, the spread in powder sizes (as measured by σ_g) also increases (Fig. 15). This spread has been taken as indirect evidence for the presence of stable particle sizes in the powder after the completion of secondary breakup (Ref 5, 7, 8, 21).

Particle Morphology

The morphology of atomized aluminum powders is influenced strongly by the amount of oxygen present in the gas phase during atomization. Particles atomized in an inert gas show spherical features, whereas air-atomized particles are of irregular shape (also known as "nodular" powders). This effect of oxygen on morphology has been attributed to the pinning effect of the oxide nuclei that form on the droplets before they have solidified (Ref 23). Many such nuclei form rapidly on a droplet when there is a high level of oxygen in the gas phase leading to effective pinning at those points. Whereas at low oxygen levels or in inert gas, the rate of oxidation would be slow and not cause pinning in which case surface tension forces would be able to maintain the spherical shape of the droplet until solidification. Tests with gaseous atmospheres of varying oxygen content have shown that the change in morphology takes place rather sharply at an oxygen level between 2 and 4%. Powders made in a gaseous atmosphere with 2% oxygen or less show essentially the same degree of sphericity as inert gas-atomized powders. When oxygen is above 4%, the deviation sphericity approaches those levels observed in air-atomized powders. The change in shape of the particles as a function of oxygen level in gas is attributed to the distortion of the droplets by oxide formation on the surface. Brunauer-Emmet-Teller (BET) surface area measurements indicate that the change in morphology takes place at an oxygen level of $\sim 2\%$ in the case of pure aluminum powders (Fig. 16).

Fig. 16 Influence of oxygen content of the gaseous medium on BET surface area of aluminum powders

Particle size and superheat are also known to influence the degree of sphericity of powder particles. Smaller particles tend to be closer to spherical than larger particles made under the same conditions.

Another feature of atomized aluminum powders, particularly important in milling applications, is the surface quality of the particles. Finer powders tend to have excellent surface quality. In others, cells can be seen.

Satellites form by warm/cold welding of smaller particles onto large particles during atomization. If the collision takes place before the larger particle has solidified, the satellite particle will be embedded.

Specific Surface Area. The specific surface area of aluminum powders is determined by the size distribution and the morphology of the particles. Powders atomized in air show a larger specific surface than inert gas-atomized powders due to the irregular shape. Figure 17 shows specific surface area of aluminum powders measured by the method of gas adsorption (BET). Fine air-atomized powders can have specific surface area values approaching $1\text{m}^2/\text{g}$. Medium sized powders are typically in the 0.2 to $0.4\text{m}^2/\text{g}$. For spherical powders at any given mass median diameter, the specific surface area values are about one-half of that of air-atomized powders.

Fig. 17 BET surface area for aluminum powders atomized in air and in inert gas

It is possible to estimate the surface area (S) of atomized powders from the distribution of particle sizes. This is related to the Sauter mean diameter d_{vs} that was defined above. For powder particles of perfect spheres, the relationship is:

$$S = \rho d_{vs}$$

Because atomized aluminum powders are not geometrically perfect spheres, they show a greater surface area. For inert gas-atomized powders, a factor of 1.3 leads to good estimates (Ref 21). A greater factor in the range of 2.6 to 3.5 is needed for the irregularly shaped air-atomized powders.

Surface Oxide Content

Aluminum reacts readily with moisture or free oxygen in the air during manufacture to form an oxide coating on the powder surface. The amount of surface oxide formed during atomization is strongly dependent on the oxygen level of the atomizing atmosphere and particle size of the powder produced. The oxygen content of fine powders atomized in air can approach 1% level by weight (Fig. 18). For coarser powders, 0.4% oxygen is more typical. A mean oxide thickness can be calculated from the oxygen content of the powder if the specific surface area has also been determined. It is then found that the thickness of oxide is, in fact, greater for coarser powders despite the lower overall oxygen content (Fig. 19). Finest powders under $10\ \mu\text{m}$ show a mean oxide thickness of 4 to 5 nm, whereas with coarser powders, the thickness can reach 10 nm.

Fig. 18 Oxygen content for aluminum powders

Fig. 19 Mean oxide thickness for aluminum powders

Spherical powders, atomized in an inert gas, contain substantially less oxygen compared to air-atomized powders. This is in part due to the smaller specific surface area of these powders. However, when compared to the mean oxide thickness, the oxide is actually between 2 and 5 nm thinner with relatively little dependence on the size of the powder.

While the mean oxide thickness is useful for comparison between different powders, it does not provide any information on the nature of the oxide skin. Indeed, recent observations have indicated that the oxide on aluminum powders is not a uniform thickness (Fig. 20). Most of the surface is covered with a thin oxide film with interspersed high hills up to 20 nm thickness (Fig. 21). The high hills represent the oxide that forms at discrete nucleation sites while the droplet is still in the molten state. As noted above, the distortion of the droplets by the nuclei is considered to be the cause of the irregular morphology of the air-atomized powders. The space between the mounts is covered by a thin skin that mostly forms in the solid state. A similar description has been offered for alloyed powders. The greater mean thickness observed in coarser air-atomized powders is consistent with this mechanism because they will have spent a longer period in the molten state exposed to oxygen.

Fig. 20 Simplified model of nonuniform oxide layer consisting of thick islands on a thin skin

Fig. 21 Model of oxide formed on gas-atomized $\text{Al}_5\text{Mn}_6\text{Cr}$ powder particle. (a) In the as-atomized state. (b) After exposure to a humid atmosphere. Source: Ref 24

Temperature of the metal would obviously have a bearing on the amount of oxide formed in powders. The results relate to material obtained in regular atomizing conditions with a superheat of 150 to 200 °C. If higher temperatures were to be employed, higher oxide levels would be expected.

The surface of the aluminum powder is hygroscopic and will react with moisture to form $\text{Al}(\text{OH})_3$ by hydration of the oxide and corrosion of the metallic aluminum especially in fine powders. A minimum relative humidity of 60% is needed for hydration promoted by prolonged exposure to moisture and temperature. The presence of manganese and chromium has been found to sharply decrease the formation of $\text{Al}(\text{OH})_3$ in alloyed powders.

Chemical and Physical Properties

The chemical compositions of unalloyed atomized aluminum powders are shown in Table 1. Iron and silicon are the major contaminants for both regular and high-purity powders. In many cases, atomizers have access to molten metal from a nearby aluminum smelter for regular purity metal grades. For high-purity powder, metal is typically bought in the form of purified ingots (sows) and prepared in furnaces that are suitably lined.

Table 1 Typical chemical analyses of atomized aluminum powders

Type of powder	Composition, wt%			Other metallics	
	Aluminum	Iron	Silicon	Each	Total
Atomized powders					
Typical	99.7
Maximum	...	0.25 ^(a)	0.15 ^(a)	0.05	0.15 ^(a)
High-purity atomized powders					
Minimum	99.97

(a) Iron plus silicon, 0.30 wt% max

High-purity aluminum is resistant to attack by acids, but it dissolves in a mixture of nitric and hydrochloric acids. Solutions of alkali hydroxides rapidly attack aluminum, with evolution of hydrogen and formation of the corresponding soluble aluminate. Aluminum reacts vigorously with bromine and iodine to form aluminum halides. Dry, oxygen-free chlorine or hydrogen chloride gas also reacts with aluminum to form aluminum chloride. Finely divided aluminum can react violently when exposed to halogenated hydrocarbons, such as methylene chloride and carbon tetrachloride, especially if the operation is carried out under pressure.

Aluminum is stable in air because of its thin, natural oxide film. In finely divided powder form, however, aluminum is more chemically reactive and hydrates when exposed to moisture as described above. Powders also react with water to liberate hydrogen and form aluminum hydroxide and release heat in the process.

Physical Properties. The physical properties of aluminum and pure aluminum powders are listed in Table 2. The real density of aluminum powder approaches that of the base metal, but both apparent density and tap density vary as a function of particle size distribution.

Table 2 Typical physical properties of atomized aluminum powders

Wrought density (metal), kg/m³	2700
Melting point, °C (°F)	660 (1220)
Boiling point, °C (°F)	2430 (4410)
Surface tension at 800 °C (1470 °F), N/m	0.865
Apparent density, kg/m³	800-1300
Tap density, kg/m³	1200-1500
Melting point of oxide, °C (°F)	2045 (3720)
Oxygen content, wt%	0.1-1.0

Explosion Potential

Many materials, including metals, polymers, and composites, are potentially explosive in the powdered form. These dusts may be the product of a given process or an unwanted byproduct. Safe handling of potentially explosive powders requires recognition of the hazards, proper handling techniques, and awareness of explosion prevention methods and fire fighting techniques.

The typical explosion occurs due to the simultaneous occurrence of the following:

- A dust cloud
- An oxygen-containing agent
- An ignition source

Common fuels include flammable gases, degradation by products, plastics and other carbonaceous particles, vapors deposited during alloying, or other molten metal handling operations, and aluminum or other metal dust cloud or layer. Common oxidizers include oxygen containing polymers, salt oxides, metal oxides (like Fe_2O_3), carbon dioxide, water, and, of course, air. Typical igniters include hot surfaces, electric or static arcs, spontaneous combustion, pyrophoric materials, impact sparks, thermite reactions, and matches and lighters.

The probability of explosion for different materials is ranked by the United States Bureau of Mines as severe, strong, moderate, weak, and none. These ratings only describe the probability of an explosion occurring as a function of the minimum amount of airborne material required to initiate and sustain a catastrophic reaction. These ratings do not describe the force of their action.

Aluminum, magnesium, and lithium have severe ratings. They are aggressive reducing agents whose reactions occur with a drastic release of energy. On the other hand, copper, stainless steel, and nickel do not oxidize readily and therefore are low on the explosibility list. In Table 3, we compare these metal powders to nonmetallic materials.

Table 3 Relative explosibility of various dusts

Material	Lower explosive limit, oz/ft ³	Rate of pressure rise, psi
Aluminum	0.045	20,000
Magnesium	0.030	15,000
Polyethylene	0.020	7,500
Flour	0.050	3,700
Coal	0.050	2,000
Coffee	0.085	150

1 oz/ ft³ = 1 kg/m³. 1 psi/ s = 6.9 kPa/ s

The rate of pressure rise is the main property that separates metal powders like aluminum and magnesium from organic materials like plastics and flour. If corn flour can destroy a silo at 3,700 psi/s, imagine what a metal dust at 5 to 6 times that will do!

Explosibility is particle size dependent, as noted in Fig. 22. One of the first rules used to predict explosibility potential is to characterize the amount of material finer than 200 mesh (75 μm) in a sample. Two things become apparent. First, below 10% -200 mesh, aluminum powders have typically shown no explosion hazards. Second, above the 10% level, the minimum amount required drops exponentially to a strong hazard, above 40%, the explosion probability is at the severe level.

Fig. 22 Effect of aluminum powder particle size on explosibility. Shown by comparing lower explosion limit with the percentage of particles less than 200 mesh in size

Preventive measures must be geared at controlling and/or eliminating as many of the legs of the triangle as possible: the fuel, the oxidizer, and/or the igniter. Table 4 shows several properties of aluminum that need to be taken into consideration when establishing preventive measures.

Table 4 Explosibility characteristics of aluminum powders

Minimum concentration (lower explosive limit), kg/ m ³ (oz/ ft ³)	0.045 (0.045)
Minimum igniting energy, mJ (cal)	50 (0.012)
Ignition temperature of cloud, °C (°F)	650 (1200)
Ignition temperature of layer, °C (°F)	760 (1400)
Maximum explosion pressure (gage), kPa (psig)	503 (73)
Maximum rate of pressure rise, MPa (psi/s)	140 (20,000 +)

Prevent formation of dust clouds when handling explosive powders. Housekeeping is the most effective prevention method. Using plant air to blow away dirt is prohibited. Natural hair brushes should be used to clean up work areas. Metal dust pans or containers are preferred.

Eliminate/Control Ignition Sources. The most obvious sources include: hot surfaces, smoking, and electrical grounding of equipment. More rigorous items include: The need for special nonsparking hand tooling, dust-tight/explosion-proof electrical switches, connectors, and other equipment, selective use of conductive floors and attention to welding and torching operations.

In the event of a fire or explosion, some simple rules for metal dusts are:

- Know and recognize the hazard
- Evacuate and let the event run its course

- For small, localized fires, initiate alarm procedure first and then only use Class D fire extinguishers or dry inert granular material (for example, sand) to smother the fire.
- *Do not use water.* Water reacts with aluminum and many other finely divided metals to form hydrogen, which is an even worse problem, and water usually comes out of the hose under pressure. This in turn creates a dust cloud that can turn a simple metal fire into a dust explosion.

Your local fire department should be aware of the hazards around metal fires and prepared in proper fire fighting methods.

Production of Aluminum and Aluminum-Alloy Powder

A. Ünal, D.D. Leon, T.B. Gurganus, and G.J. Hildeman, Aluminum Company of America

Applications

Aluminum powders have physical and metallurgical characteristics related to their method of manufacture that make them extremely important in a variety of applications. They can propel rockets, improve personal hygiene, make computers more reliable, refine exotic alloys, and make the family sedan or the newest Air Force fighter lighter in weight and more efficient while providing beauty and protection against sunlight and moisture. Powders, in the form of P/M parts for structural and nonstructural applications, also hold the key to some of the most exciting new developments in the aluminum future.

As powder, aluminum is used in blasting agents where the concentrated energy from the high heat of combustion allows explosive manufacturers to better match energy release to specific rock characteristics or mining conditions. This eliminates or minimizes over or under blasting and reduces total rock breakage costs. This same energy release characteristic makes powders an important element in the solid fuel rockets used for national defense and to launch space probes. Each launch of the Space Shuttle requires 350,000 pounds of aluminum powder. Energy release is also an important criteria in the metallurgical industry, where aluminum powder is used as a heat source as well as a reducing agent. Such applications include production of ferro-alloys like ferro-columbium, pure metal, such as chromium and nonferrous alloys like boron-chromium. Other exothermic applications include hot topping compounds, stress relieving, exothermic welding, and powder lancing.

Powder compounds derived from aluminum powders also find a wide variety of uses in the chemical and plastics industries. These uses range from highly selective catalysts through powerful reducing agents to inert fillers. Aluminum alkyls, produced from powders, are a group of compounds used as feedstock in the production of biodegradable detergents and plasticizers. Aluminum chlorhydroxide and aluminum glycinate are widely used constituents in deodorant and antiperspirant formulations. As a filler for epoxy resins, aluminum powders can reduce shrinkage, increase thermal conductivity by an order of magnitude and reduce thermal expansion as well as reduce permeability and swelling attributable to water, oxygen, or other penetrants.

Powders flattened into tiny flakes by steel balls in a rotating mill provide the metallic pigments for paints and coatings. Leafing pigments, processed to rise to the surface of paint, reflect heat in roof coatings and can protect nonaluminum

structures, such as bridges and tanks, from the weather. Nonleafing pigments, processed to remain suspended in paint or coating, provide the metallic finish for cars, trucks, and other items, such as inks and football helmets. The ability to tailor the pigment size and shape to achieve variations in appearance gives product developers an extra degree of freedom in design.

In the electronics area, aluminum nitride P/M ceramics are excellent candidates for electronic packages and substrates, especially with multichip modules, because of thermal expansion and heat transfer characteristics. The use of improved thermal conductivity to yield a reduction in operating temperatures of a typical module by 10 °C (20 °F), will double the reliability of the circuit.

The most exciting application for aluminum powders is in the production of P/M parts for structural and nonstructural applications in the transportation and commercial areas. These press and sinter products, blends of aluminum and elemental alloy powders, are pressed into intricate configurations and sintered to yield net or near-net shapes. There are two basic classes of commercial press and sinter aluminum alloys: 601AB (Al-0.25Cu-0.6Si-1Mg) and 201AB (Al-4.4Cu-0.8Si-0.5Mg). Alloy 601AB displays moderate strength (tensile strength is 237 MPa, or 34.5 ksi) with excellent corrosion resistance, while alloy 201AB develops high mechanical properties (tensile strength is 331 MPa, or 48 ksi) in both the as-sintered and heat-treated conditions.

Parts produced from these materials have the exceptional properties associated with aluminum: light weight, corrosion resistance, high thermal and electrical conductivity, good machinability, and excellent response to a variety of finishing processes. They also offer competitive raw material prices on a cost per unit volume basis.

However, the primary driver for the application of P/M aluminum is the ability to produce complex net or near-net shape parts that need minimal or no machining. This capability makes P/M parts cost-competitive with many castings, extrusion, forgings, and machine-screw products. In addition, the P/M parts can be further processed by hot or cold forging to eliminate porosity and improve strength. Mechanical properties of such products compare favorably with those of conventional wrought alloys and are superior to those of typical press and sinter parts. The niche for P/M forgings is in the strength/cost gap between castings and conventional forgings, and in applications such as connecting rods, gears, and pistons.

Newer aluminum powder products take advantage of rapid solidification technology to produce prealloyed P/M materials with strength, toughness, fatigue, corrosion resistance, and elevated temperature performance not achievable with conventional wrought alloys. These powders can be blended with nonmetallic powders to produce P/M-based metal-matrix composites (P/M MMC) that have "next generation" properties in the areas of stiffness, fatigue, wear, and physical property control. Such new materials have been aimed at the aerospace market and have found uses in both new aircraft platform production and aging aircraft retrofit programs. The relatively limited applications coupled with high projected costs have resulted in reduced commercial interest by both producers and users. The technology, however, stands ready to solve the tough next generation product needs, and the ultimate progression of market use from aerospace to the commercial area could generate significant, high volume applications.

Aluminum powder products span an incredible range of uses from beautification to national defense and from the mundane to the highly sophisticated. Life without these products would not be the same, and they are the key to exciting new developments for the future.

Production of Titanium Powder

J.H. Moll and C.F. Yoltan, Crucible Research Center, Crucible Materials Corporation

Introduction

TITANIUM is used for many aerospace and nonaerospace applications because of an attractive combination of low density, good mechanical properties, and good corrosion resistance. More recently, titanium aluminide alloys are being developed for applications requiring high-temperature strength. In general, titanium is expensive to produce and fabricate. With the advent of the titanium aluminide alloys, this is further complicated by segregation problems in these highly alloyed materials. Powder metallurgy (P/M) processing of titanium offers potential solutions to these problems. One area for cost reduction with P/M processing is the production of near-net shapes eliminating yield losses associated with ingot breakdown, forging, and machining. With highly alloyed materials such as the titanium aluminide alloys, processing from ingot requires repeated homogenizing heat treatments and hot working operations to minimize segregation. Powder metallurgy products are inherently homogeneous and do not require any special processing to eliminate segregation. Powder metallurgy processing also provides an opportunity to produce alloys and structures that are not possible through conventional ingot processing.

Titanium powder is produced by a variety of processes. These include chemical reduction, hydride/dehydride, gas atomization, plasma-rotating electrode, and mechanical alloying. This article will describe each of the processes, the characteristics of the resulting powder, and some end applications.

Production of Titanium Powder

J.H. Moll and C.F. Yoltan, Crucible Research Center, Crucible Materials Corporation

Chemical Reduction

A primary source of titanium powder is "sponge fines," so called because of their origin and appearance (Fig. 1). Sponge fines are small irregular particles of nominally pure titanium produced during the production of titanium sponge from titanium tetrachloride. The commercial production of titanium metal involves the chlorination of natural or synthetically produced rutile, TiO_2 , in the presence of carbon (Ref 1). The resulting titanium tetrachloride is reduced to metallic titanium by the Kroll process using magnesium (Ref 2) or by the Hunter process using sodium (Ref 3). Most of the remnant chloride is removed by vacuum distillation or by water leaching. The final sponge fines typically contain 0.12 to 0.15 wt% Cl. The inherent chloride content of conventional sponge fines can lead to incomplete densification and limited fatigue properties. A typical screen analysis and chemical composition of sponge fines produced by sodium reduction are given in Tables 1 and 2, respectively. Table 3 gives tensile properties of Ti-6Al-4V compacts produced from sponge fines and aluminum-vanadium master alloy.

Table 1 Screen analysis of sodium reduced titanium sponge fines

Mesh size (U.S.)	Particle, μm			Weight percent retained
+80	+177			0
-80	+100	-177	+149	0.1

Commercially pure (CP) titanium is also being produced in Russia from titanium dioxide by reduction with calcium hydride (Ref 4) as follows:

The reaction is performed at temperatures ranging from 1100 °C (2000 °F) to 1200 °C (2200 °F). Prealloyed powder is produced by reacting mixtures of oxides of different elements or master alloy powders. Because the process does not use titanium tetrachloride, the powders contain low levels of chlorine. Table 4 gives the composition of CP titanium and prealloyed Ti-6Al-4V powders made by the process. The process also allows the direct production of titanium aluminides.

Powder particles made by the calcium hydride process (Fig. 2) have a spongy morphology and consist of a conglomeration of small particles fused together during the reaction process. The particles are readily sintered due to their irregular shape and large surface area. Figure 3 shows the particle size distribution for CP titanium. The average particle size is 41 μm . Fully dense articles with the Ti-6Al-4V composition have been made by synthesizing the composition from a blend of metal hydride reduced CP titanium and master alloy powders and consolidating by hot isostatic pressing. Table 5 shows mechanical properties of the fully dense products.

Sponge fines with <400 ppm chlorine can be produced by an electrolytic process (Ref 5). Reportedly, low chlorine sponge can also be produced by a reaction of TiO_2 with fluorine salts followed by reduction with aluminum in a zinc carrier medium (Ref 1, 6).

Figure 4 shows elemental powders are being used to manufacture a variety of corrosion resistant fasteners. A technology has also been developed to make porous titanium plates for a variety of applications including supports for the electrolyte membrane in water electrolysis cell technology (Ref 4). Titanium powders have also been evaluated for use in automotive applications such as valve spring retainer caps and connecting rods. Reportedly, the parts demonstrated the necessary mechanical properties and provided significant weight savings (Ref 7).

Fig. 4 Titanium parts made from powder made by the calcium hydride reduction process. Courtesy of AdMa International Inc.

Fully dense parts can be made from blended elemental powder using a cold plus hot isostatic process designated CHIP (Ref 8). The process, developed by Dynamet Technology, involves cold pressing of the blended powders in inexpensive elastomeric tooling under hydrostatic pressure. The "green" preform is then sintered to 95% minimum density. Full density is attained by hot isostatic pressing and the near-net shape is machined to final dimensions. Figure 5 shows a missile component made by the CHIP process.

Fig. 5 Sidewinder missile component fabricated by the CHIP process. The left part is the near-net machining preform; the right part is the finished machined component. Courtesy of Dynamet Technology

Production of Titanium Powder

J.H. Moll and C.F. Yoltan, Crucible Research Center, Crucible Materials Corporation

Hydride/Dehydride Process

The hydride/dehydride (HDH) process for making titanium powder is based on the reversible interaction of titanium and hydrogen. Titanium has a very high affinity for hydrogen and is easily hydrogenated by heating titanium in a hydrogen atmosphere. Hydrogenated titanium is very brittle and can be crushed to a fine powder. The hydrogen can then be simply removed by heating the powder in a dynamic vacuum. The minimum hydrogenation temperature for commercially pure titanium is about 400 °C (750 °F) at 0.007 MPa (1 psi) positive hydrogen pressure. The time required varies depending upon the cross-sectional area of the starting stock. Typically, machine turnings can be hydrogenated in four hours. Starting stock can be a variety of pure or prealloyed titanium materials such as ingot, billet, scrap, or machine turnings. Care must be taken to ensure the cleanliness of the starting material because any extraneous material may carry over into the resulting powder (Ref 9). The resulting powder, Fig. 6, is angular and is amenable to cold compaction and subsequent densification by sintering and/or hot isostatic pressing. Figure 7 shows a particle size distribution for commercially pure titanium powder produced by the HDH process. Hydride/dehydride commercially pure titanium powder has been used to make Ti-6Al-4V and Ti-6Al-6V-2Sn by blending with the appropriate master alloy, cold isostatic pressing, sintering, and hot isostatic processing (Ref 10). Table 6 gives the compositions of the synthesized compositions, and the room temperature tensile properties of these materials are given in Table 7.

Gas Atomization

A gas atomization process for titanium, designated TGA, was developed by Crucible Materials Corporation (Ref 11, 12, 13). The TGA process involves some unique characteristics such as:

- Vacuum-induction skull melting a charge in a water-cooled copper crucible
- Tapping the furnace through the bottom into a nozzle
- Induction heating of the metal nozzle

The resulting molten metal stream is atomized with inert gas. Starting stock for atomization can be virgin raw materials or prealloyed materials, such as ingot or bars. As the charge is melted in the crucible, a thin skull forms at the crucible wall so that the molten titanium is always contained in a solid skull of the same composition. After the charge is fully molten, it can be held in the molten state for an extended time to ensure complete homogeneity of the melt. The vigorous stirring action produced by the strong inductive field and the ability to hold the metal in the molten state for an extended period of time are particular advantages of the melting method.

To initiate the pour in the TGA process, power to a second induction coil causes localized melting at the center of the bottom of the skull. The liquid metal is then bottom poured through a metal nozzle and free falls through the atomization die, which contains a ring of high-pressure jets. The force of the atomization gas disintegrates the stream into tiny droplets, which rapidly solidify into powder particles as they fall through the cooling tower. The atomization gas carries the powder particles into a cyclone collector, and they are finally collected in a cooled canister.

The powder produced by the TGA process is spherical and free flowing (Fig. 8). Figure 9 shows the size distribution of various titanium and titanium aluminide alloys. Typical tap densities for gas atomized titanium alloys range from 60 to 70% of solid density. Flow rates, depending on the alloy, range from 25 to 35 s, as measured according to ASTM B 213. Interstitial element levels in gas atomized titanium and titanium aluminide alloys can be held to maximums of 800 ppm oxygen, 150 ppm carbon, and 100 ppm nitrogen. There is essentially no increase in carbon, nitrogen, or hydrogen over the melt stock used for atomization. The increase in oxygen content from the starting stock to -35 mesh powder is ~ 200 ppm. Figures 10, 11, and 12 show the effect of powder particle size on oxygen content of Ti-6Al-4V and Ti-48Al-2Cr-2Nb (at.%), respectively. As can be noted, oxygen content increases with decreasing particle size due to increasing surface area. Nitrogen content is unaffected by particle size.

Fig. 12 Microstructure of hot isostatically pressed Ti-48Al-2Cr-2Nb (at.%) powder made by gas atomization

The TGA process has been used to produce a wide variety of materials such as CP titanium, conventional alpha-beta and beta alloys, and alpha two and gamma titanium aluminide alloys, as well as specialized compositions. Consolidation of the powder results in a highly uniform microstructure, as exemplified with a gamma titanium aluminide alloy in Fig. 12. Gas atomized gamma titanium aluminide powder is being considered for producing forging and machining preforms and near-net shapes for engine application. A process is also being developed to produce gamma titanium aluminide sheet from hot isostatically pressed plate (Ref 14); see Fig. 13. The P/M process has been reported to be more efficient and exhibit higher yields than sheet produced from ingot. It is also reported that the strength and ductility of the P/M sheet are comparable to sheet produced from ingot. Gamma titanium aluminide sheet is being evaluated for inner shrouds on the F-119 engine for transition into production engines for the Joint Strike Fighter and F-22A (Ref 15). Other potential applications for TGA powder include metal matrix composites made by induction-plasma deposition (Ref 16, 17) and tape casting (Ref 18). Titanium matrix composites are being considered for use in a variety of rotating and nonrotating parts in turbine engines to reduce weight and increase stiffness (Ref 19). Figure 14 shows the microstructure of a Ti-6Al-4V/SiC composite ring and its microstructure made by tape casting using gas atomized powder.

Fig. 14 Ring containing a composite insert (a) and microstructure of the Ti-6Al-4V/SiC composite (b) made by tape casting using gas atomized powder. Courtesy of Atlantic Research Corporation

Sumitomo Sitix has also developed a gas atomization process for titanium (Ref 20, 21). In this process, a bar of titanium sponge or titanium alloy is lowered through an induction coil. As the bar melts, argon or helium gas jets break up the molten metal into droplets, which solidify as they are swirled within the atomization chamber. The resulting powder is fine with a mean particle size of $\sim 70 \mu\text{m}$. The process has been used to make CP titanium, Ti-6Al-4V, and Ti-36Al.

Plasma-Rotating Electrode Process

The plasma-rotating electrode process (PREP) is a centrifugal atomization process for making titanium prealloyed powder developed by Starmet (Ref 22). In this process, a helium plasma is used to melt the end of a rapidly rotating bar and molten droplets are spun off and solidify in flight in a helium atmosphere (see the article "Rotating Electrode Process" in this Volume). Melting and atomization are conducted in a circular stainless steel tank ~ 2440 mm in diameter maintained at a positive pressure of helium. The electrodes are prealloyed bars nominally 60 to 65 mm in diameter and are spun at speeds up to 15,000 rpm.

The PREP powder (Fig. 15) is spherical, has good flow characteristics, and a tap density of $\sim 65\%$ of theoretical density. The size of the powder particles depends on the alloy, the electrode diameter, and the rotational speed at the time of atomization. Typical sizes for Ti-6Al-4V powders are between 100 and 300 μm with a d_{50} of $\sim 175 \mu\text{m}$ (Ref 23).

Fig. 15 Ti-6Al-4V powder made by the plasma-rotating electrode process

Compared to gas atomized powder, PREP powder is relatively coarse. Various process modifications have been investigated to produce finer powder. The use of a large diameter disk electrode rather than a bar electrode has been reported to decrease the mean particle size by more than 40% and to reduce cost of input material (Ref 23). In another process modification, the metal droplets were quenched into liquid argon. The result was a major reduction in powder particle size (Ref 23). In yet another modification, gas atomization was coupled with the rotating-electrode process (REP), as shown in Fig. 16. The REP powder process is similar to PREP, except that a tungsten arc is used instead of a plasma to melt the end of the rotating electrode (Ref 22). As shown in Fig. 17, the yield of $-44 \mu\text{m}$ titanium powder increased from less than 1% with regular REP to greater than 20% with gas atomization assisted REP.

An engine mount support (Fig. 18) made from PREP Ti-6Al-4V powder has been qualified for use on the F/A-18A Hornet fighter aircraft (Ref 25). Table 8 gives mechanical property data used to qualify the hot isostatically pressed near-net shape. The PREP powder is also used to produce a porous coating on hip prostheses for bone ingrowth (Fig. 19).

Mechanical Alloying

Mechanical alloying is a high-energy ball milling process, which can be used to produce materials with unique compositions and microstructure. The process was originally developed to produce nickel and iron-base oxide-strengthened alloys (Ref 26). The application of the process to titanium-base alloys is relatively recent and generally involves loading a mix of powders and a grinding medium (usually hardened steel balls) into a container under a protective argon atmosphere. A small amount of a process control agent is normally added to prevent vent excessive cold welding of the powder particles during the milling operation. The material is then processed on a high-energy ball mill. Alloying occurs as the result of repeated welding, fracturing, and rewelding of the powder particles (Ref 27). Much of the work to date has involved the development of unique structural and microstructural characteristics such as supersaturated solid solutions, metastable crystalline phases, dispersion strengthened alloys, amorphous phases, and nanostructured materials. Extensive reviews of the application of mechanical alloying to titanium are contained in Ref 27, 28, 29, 30. Mechanical alloying is also being studied as a technique for producing nanostructured intermetallic alloys (Ref 30, 31) and composites such as Ti-6Al-4V/SiC (Ref 32) and titanium aluminide/titanium silicide (Ref 33). Figure 20 shows an example of mechanically alloyed powder. Figure 21 shows an example of the extremely fine microstructure that can be attained using mechanically alloyed powder.

Production of Nickel-Base Powders

Introduction

NICKEL-BASE POWDERS are produced by the decomposition of nickel carbonyl, by the reduction of aqueous solution of a nickel salt with hydrogen under pressure (the Sherritt process), by inert gas or water atomization, and by mechanical alloying. Of these, decomposition of nickel carbonyl and the Sherritt process, which produce metallic nickel from its ore, are the most important commercially. This article briefly reviews each of these methods.

Production of Nickel-Base Powders

Carbonyl Vapormetallurgy

John H. Tundermann, Inco Alloys International, Inc.

The production of nickel powders by the decomposition of nickel carbonyl dates back to a process developed in 1889 by Ludwig Mond and his coworkers Carl Langer and Friedrich Quincke. According to Mond (Ref 1), the firm of Brunner, Mond, and Company was endeavoring to prepare chlorine from ammonium chloride, which in turn was obtained as a by-product of the ammonia-soda process, widely known as the Solvay process.

One of the obstacles to the successful production of chlorine was the unusually rapid corrosion of the nickel valves on the brick-lined tanks in which ammonium chloride was vaporized. Laboratory study of this corrosion proved that it resulted from the small amount of carbon monoxide used to sweep ammonia from the vaporizing tanks. Carbon monoxide was partially converted into carbon dioxide, and a black mixture of nickel and amorphous carbon was deposited. This observation led to a more elaborate study of the reaction of carbon monoxide with finely divided nickel.

Mond and coworkers found that four molecules of carbon monoxide at atmospheric pressure and at temperatures between 40 and 100 °C (105 and 212 °F) react with active nickel to form a colorless gas, nickel tetracarbonyl:

They further demonstrated that the reaction is readily reversible by heating the nickel tetracarbonyl to temperatures in the 150 to 300 °C (300 to 570 °F) range to yield pure nickel and carbon monoxide:

Nickel that has been in contact with air does not react with carbon monoxide, which is why carbonyls were not discovered earlier.

Encouraged by their success in preparing nickel tetracarbonyl, Mond and coworkers immediately attempted to prepare carbonyls from all the metals at their disposal. However, it was Berthelot who first announced the formation of a volatile

compound of carbon monoxide and iron, iron pentacarbonyl, in June 1891. Subsequent discoveries were made of many metal carbonyls, including cobalt, iron, molybdenum, and ruthenium carbonyls.

After preliminary laboratory trials, Mond built an experimental plant near Birmingham, England, and subsequently developed the Mond-Langer process for separating nickel from Canadian matte. By 1895, the plant successfully produced $1\frac{1}{2}$ tons of nickel weekly from Canadian matte containing 40% Ni. Mond subsequently opened a refinery in Clydach, Wales (Mond Nickel Company), and during the 27 years the refinery operated, the plant processed more than 82,000 metric tons (90,000 tons) of nickel in the form of pellets that exhibited greater purity than nickel produced by any other commercial process at that time.

In this process, which in modified form is still used at the refinery in Clydach, nickel oxide produced from roasting nickel sulfide is reduced to nickel sponge by hydrogen; activated by sulfiding, and volatilized as carbonyl in an atmospheric reactor. Nickel carbonyl produced in this manner is decomposed directly in the powder and pellet units as part of a continuous process of refining.

Production of Nickel-Base Powders

Metal Carbonyls

Many metals form carbonyls; in fact, all of the metals of the first, second, and third transition metal series have been converted into one or more types of carbonyls. Additionally, several of the lanthanides and actinides have formed carbonyls. Nickel forms a single carbonyl, $\text{Ni}(\text{CO})_4$, in its zero valent form:

Nickel also forms a hydridocarbonyl, $\text{H}_2\text{Ni}_2(\text{CO})_6$, where nickel has an oxidation number of -1. The carbon monoxide ligands in nickel carbonyl can be replaced by other ligands such as phosphines, phosphites, and certain unsaturated hydrocarbons where a high degree of electron density is capable of allowing "back bonding π ," as well as the conventional σ bonding typical of donor ligands.

The iron penta compound, iron pentacarbonyl or $\text{Fe}(\text{CO})_5$, rapidly condenses into the bimetallic species diiron nonacarbonyl $\text{Fe}_2(\text{CO})_9$, which on heating further condenses into the trimetallic triiron dodecacarbonyl $\text{Fe}_3(\text{CO})_{12}$. The nonacarbonyl compound exhibits two types of carbonyl bonding, the donor σ type and the bonding bridge type (π):

Chromium, molybdenum, and tungsten each form a single hexacarbonyl, a hexacoordinated octahedron. Cobalt forms a binuclear carbonyl, dicobalt octacarbonyl, $\text{Co}_2(\text{CO})_8$:

which condenses to the tetranuclear species, containing bridged cobalt atoms:

The condensing continues with the formation of what is known as a cluster carbonyl:

Several types of carbonyl clusters exist; one of the largest is the tetracapped pentagonal prism:

Some metals have avoided becoming "pure" carbonyls to date, but halo derivatives of copper, gold, platinum, and palladium have been synthesized:

Heterocarbonyls also have been produced, including:

Metal carbonyl carbides also exist, such as $\text{Fe}_5(\text{CO})_{15}\text{C}$ and the dicarbide clusters $\text{Ru}_{10}\text{C}_2(\text{CO})_{24}$, $\text{Co}_{13}\text{C}_2(\text{CO})_{24}$, and $\text{Rh}_{15}\text{C}_2(\text{CO})_{23}$. Another example of metal carbonyl is the dinitrogen derivative:

A complete list of all the metal carbonyls that can be formed is beyond the scope of this article. The above examples are provided to illustrate the diversity of the chemical forms of metal carbonyls.

Production of Nickel-Base Powders

Metal Carbonyl Formation and Decomposition

While the equation for metal carbonyls is generally written as follows, the mechanism is far more complex than the equation implies:

At room temperature, carbonyls typically form liquids, vapors, and colored crystals. Carbonyls may be formed, volatilized, and condensed in a continuous process to separate them from the inert constituents of the feed. Some must be separated with elaborate techniques, while still others are intractable materials. They may be formed as liquids or as solutions in organic solvents and separated from inert solids by filtration. Crude carbonyls are separated from each other and residual impurities by distillation, sublimation, recrystallization, or selective solution of the carbonyl. Purified carbonyls are decomposed by heating into the carbon monoxide and pure metal. When a metal carbonyl can be separated from its impurities, subsequent decomposition generally results in high-purity metals. Exceptions to this include the formation of carbides.

Nickel tetracarbonyl was the first carbonyl discovered in the 1890s. Iron pentacarbonyl and cobalt octacarbonyl followed soon after; these remain the only carbonyls whose singular chemical properties have been applied commercially to extractive metallurgy, although it is speculated that ruthenium separation by carbonyl formation should ensue. In the formation of nickel tetracarbonyl, a mixture of freshly prepared nickel metal and nickel sulfide is heated in the presence of carbon monoxide.

Thermal decomposition reactions of commercial interest for cobalt, iron, and nickel carbonyls occur at temperatures about 200 °C (390 °F), where carbonyls can be handled in vapor form. Under these conditions, reaction kinetics permit acceptable powder production rates to be maintained. Carbonyls are heated rapidly to the desired decomposition temperature; at this temperature, nuclei form in the vapor to provide the required sites for metal deposition.

Decomposition products are the pure metal and carbon monoxide. During decomposition in commercial decomposers, the disproportionation reaction of carbon monoxide is catalyzed by the freshly formed metals. Iron is much more active as a catalyst than either nickel or cobalt, and therefore carbon contents in nickel carbonyl-derived powder are related to the trace iron content:

Production of Nickel-Base Powders

Nickel Tetracarbonyl

The versatility of the carbonyl extraction of nickel is characterized not only by selectivity in formation, but also by the relative ease of separation and decomposition to high-purity metal. Under the conditions employed for reaction at atmospheric pressure, carbonyl-forming impurities in crude nickel metal do not enter the gas phase. Thus, extraction of nickel by its volatilization from crude metal as carbonyl vapor is a highly selective process.

For a given condition of surface activity, the rate of gaseous or liquid carbonyl formation is determined by the temperature of the reaction and increases with increasing partial pressure of carbon monoxide. Whereas the rate of carbonyl formation increases with increasing temperature, the equilibrium mole fraction of carbonyl formed decreases sharply with increasing temperature. At a given total pressure, there is an optimal temperature at which metal carbonyl will form, as shown in Fig. 1.

Fig. 1 Influence of system pressure and temperature on reaction rate in the formation of nickel tetracarbonyl. Source: Ref 2

Kinetic data for the nickel tetracarbonyl reaction can be correlated by means of a modified first-order rate equation. The ultimate degree of metal conversion of "initial surface activity" has a definite value at a given temperature and pressure, which permits the derivation of a functional relationship between surface activity and metal conversion. Substituting this relationship and integrating the first-order rate equation yields a semiempirical model for correlating nickel tetracarbonyl formation rate data at a given temperature (Ref 3):

$$\ln \frac{a^0}{a^0 - x} = K_o \left(P_{\text{coi}} - \sqrt{\frac{b P_{\text{cai}}}{K_e}} \right) t$$

where a^0 is the initial activity of the surface, b is the number of moles of carbon monoxide per mole of carbonyl, K_o is the rate constant in grams per square centimeter per hour, K_e is the equilibrium constant, P_{cai} is the partial pressure of carbonyl at the interface in torr, P_{coi} is the partial pressure of carbon monoxide at the interface in torr, t is time in seconds, and x is the fraction of metal reacted.

From an engineering design point of view, conversion of nickel to a carbonyl at a fixed temperature depends primarily on the partial pressure of the carbon monoxide present. The effect of increased system pressure on the conversion of nickel to a carbonyl has been shown experimentally and demonstrated commercially. The volume change inherent in the carbonyl reaction--four carbon monoxide molecules combining in one molecule of nickel tetracarbonyl-- also points to an increase in carbon monoxide pressure as a means of improving reaction kinetics. In addition to directly increasing the rate of reaction, increased pressure stabilizes the carbonyl, thus permitting reaction at higher temperatures for a further increase in rate. The nickel tetracarbonyl formation reaction is highly exothermic:

Accordingly, high conversion-rate commercial nickel carbonylation processes require large heat removal systems.

At room temperature, nickel tetracarbonyl is a colorless volatile liquid with a high vapor pressure. It boils at about 43 °C (109.4 °F) and begins to decompose at 60 °C (140 °F) or less, depending on conditions. It is only slightly soluble in water, but is highly miscible with many organic solvents. Some physical properties of nickel tetracarbonyl include:

Chemical formula	Ni(CO) ₄
Color and state	Colorless liquid
Molecular weight	170.75
Nickel, %	34.37
Melting point	-25 °C (-13 °F)
Boiling point	43 °C (109.4 °F) at 101.1 kPa (751 mm Hg) 42.1 °C (107.8 °F) at atmospheric pressure
Specific gravity	1.36153 at 0 °C (32 °F) 1.27132 at 36 °C (97 °F)
Heat of formation ($\Delta_f H^{298}$)	-602.5 kJ/g · mol (-144.0 kcal/g · mol)

Nickel tetracarbonyl vapor is exceedingly toxic when inhaled; 50 ppb of the compound in the air is the maximum allowable concentration designated by the American Conference of Governmental and Industrial Hygienists. Nickel tetracarbonyl should be handled only by personnel who are familiar with its toxic properties.

The stability of metal carbonyls varies considerably. Nickel tetracarbonyl begins to liberate carbon monoxide and nickel at 0 °C (32 °F) in a vacuum, and the decomposition becomes rapid above 60 °C (140 °F) in an inert gas under atmospheric pressure. Thermal decomposition is endothermic and is markedly inhibited by the presence of carbon monoxide. The mechanism of formation of nickel powder by the thermal decomposition of nickel tetracarbonyl is complex. In the formation of powder particles from the gaseous phase, several simultaneously occurring processes exert an influence. These include the formation of complex nuclei, secondary crystallization of nickel on the surfaces of the finest particles, the interaction of particles in the crystallization process, and side reactions such as the decomposition of carbon monoxide. At a given temperature, the homogeneous part of the decomposition of nickel tetracarbonyl follows the rate equation (Ref 3):

$$r = \frac{K_o P_{ca}}{1 + K_g P_{co}}$$

where r is the decomposition rate in grams per cubic centimeter per hour, K_g is the adsorption constant of carbon monoxide on metal torr⁻¹, K_o is the rate constant in grams per square centimeter per hour, P_{ca} is the partial pressure of carbonyl in torr, and P_{co} is the partial pressure of carbon monoxide in torr. The decomposition rate for nickel tetracarbonyl is directly proportional to the partial pressure of the carbonyl and inversely proportional to the partial pressure of the liberated carbon monoxide.

Conditions that influence the formation of the self-nucleating nickel particles during carbonyl decomposition (such as process temperature and the concentration and rate of the nickel tetracarbonyl supply to the decomposer) can vary greatly, which affects the physical and technical properties of the powders produced. Additions to the nickel tetracarbonyl gas stream sent to the decomposer can alter the mechanism by which the powder is formed, as well as its resulting morphology. For example, hydroquinone vaporized with the carbonyl acts as a free radical trap, resulting in the formation of macroparticles of nickel metal. Nickel tetracarbonyl can be photochemically decomposed to form elemental nickel by light of wavelengths shorter than 390 nm (3900 Å).

The most important industrial application of nickel tetracarbonyl is for refining nickel, in which nickel pellets and powder products are formed. Gas-plated products and a wide range of metallic and nonmetallic (nickel-coated graphite) powders can be produced by forming coatings of nickel on various surfaces by decomposing the carbonyl under special conditions. Nickel tetracarbonyl is manufactured on a limited basis to serve the chemical industry. The carbonyl serves as a catalyst for organic synthesis, as well as providing a means for the manufacture of other organonickel compounds. It also is used for vapor plating on smooth surfaces (such as plastic and metal) and to form nickel molds for the glass industry.

Production of Nickel-Base Powders

Commercial Processes

Currently, Inco Ltd. produces high-purity nickel powders by the thermal decomposition of nickel tetracarbonyl. Gaseous nickel tetracarbonyl is formed by reacting carbon monoxide with nickel concentrates under controlled conditions; subsequent thermal decomposition of the gas permits recovery of the nickel as a fine metallic powder and nickel pellets. The process, which affords a high degree of purity with respect to metallic elements other than nickel, produces nickel powders with extremely uniform particle size and structure.

The original Mond-Langer process has been greatly improved during its continued use. Commercial nickel refineries employing the carbonyl process to produce nickel powder are located on the site of the original Mond facility in Clydach, Wales, and in Copper Cliff, a subdivision of Sudbury, Ontario.

The Clydach refinery began nickel output from Sudbury cupriferrous nickel matte in 1902. Current plant feed matte is granular nickel oxide that contains small amounts of copper, cobalt, and iron, as well as siliceous matter. This refinery still uses the basic concept of the Mond-Langer process and produces nickel products using atmospheric pressure carbonyl processing. The latest innovations involve replacement of the many small hearth-type reducers and volatilizers of the original works by large rotary kilns arranged in trains of two kilns with a smaller sulfiding unit. In the initial unit of each train, the nickel feed matte is reduced to metal by a countercurrent flow of preheated hydrogen. The reduced nickel matte is then activated by sulfiding and is volatilized as carbonyl in the final kiln by a countercurrent flow of carbon

monoxide. The resulting nickel tetracarbonyl vapor is decomposed directly into pure nickel pellets and powders in reactors or decomposers.

The Copper Cliff Nickel Refinery began operations in 1973 with two newly developed techniques, including the use of top-blown rotary converters that take a 64 metric ton (70 ton) charge of feed materials. The other manufacturing method uses the Inco pressure carbonyl process for the recovery of nickel from a variety of nickel-bearing feed materials, including the removal of nickel from copper, cobalt, and precious metal concentrates. The refinery produces pellets and powder of 99.9+% nickel purity and a codecomposed iron-nickel powder.

Environmental controls at the plant include a totally enclosed process that constantly recycles all process reagents. The Copper Cliff refinery uses the same basic process chemistries, but forms nickel tetracarbonyl at high pressure, which is necessary to extract nickel in the presence of high copper concentrations.

The plant feed is a mixture of oxides and sulfides of nickel, copper, iron, and cobalt, other crude metallics, and partially processed precious metals and refinery residues that contain nickel. This mixture is charged along with coke into one of two 64 metric ton (70 ton) capacity, top-blown rotary converters, where it is melted and partly blown to slag silicates and some of the iron. The converter-treated hot material is subsequently granulated by pouring it through high-velocity water jets. At this point, the granules contain 65 to 75% Ni, 15 to 20% Cu, 2 to 3% Fe, and 3% S present as sulfides.

The metallic granules are batch-reacted with carbon monoxide at temperatures up to 180 °C (360 °F) and pressures up to 70 atm (1030 psi) in one of three 136 metric ton (150 ton) capacity rotating reactors. Nickel, and some iron, is extracted as a crude carbonyl vapor, while copper, cobalt, precious metals, and impurities are retained in the residue. Removal of iron is controlled to between 20 and 50% of the input iron level. Iron concentration in the granules rarely exceeds 4%. Cobalt in the feed does not form $\text{Co}_2(\text{CO})_8$ or $\text{Co}_3(\text{CO})_{12}$, because these compounds occur only when carbon monoxide pressures of 150 atm (2205 psi) are achieved.

Formation of nickel tetracarbonyl is quite exothermic; consequently, the reactors are water cooled. Extracted carbonyl vapor is liquefied and stored at atmospheric pressure. The carbon monoxide carrier gas also is recycled. The liquefied product stream, containing mutually soluble nickel and iron carbonyls, subsequently is pumped to distillation columns, where it is separated into nickel tetracarbonyl vapor and an iron-rich liquid carbonyl. Fractionating the crude carbonyl liquid is achieved easily, because the boiling points of the nickel and iron carbonyls are 43 °C (109.4 °F) and 102.8 °C (217 °F), respectively. The system produces nickel tetracarbonyl vapor of 99.998% purity, with the bottom liquor having nickel-to-iron ratios of up to 3 to 7. At the top of the column, nickel tetracarbonyl vapor is siphoned off and fed directly into powder decomposers. Somewhat below the top of the column, liquid nickel tetracarbonyl is taken off and either held in storage or used to feed the nickel pellet decomposers.

The powder decomposers are steel cylinders, the walls of which are heated with high-capacity electrical resistance heaters. Nickel carbonyl vapor is introduced into the top of the decomposer chamber slightly above atmospheric pressure, where it contacts the heated decomposer walls that are preset at a temperature between 250 and 350 °C (480 and 660 °F). The thermal shock decomposes nickel tetracarbonyl into nickel powder, with the release of carbon monoxide. The latter is recycled through filters to the main gas compressor to be recycled to the pressure carbonyl reactors, while the powder is collected, gas purged, stabilized with an oxide coating, and transferred to storage completely free from carbonyl and carbon monoxide.

The dangerous nature of the gaseous and liquid carbonyl compounds formed in the Inco processes is fully countered by established, effective, and practical safety measures. All product discharge systems are purged completely prior to powder and pellet packaging.

Production of Nickel-Base Powders

Powder Properties and Applications

Currently, there are four types of nickel powders produced by thermally decomposing nickel tetracarbonyl--single spikey particles, filaments, high-surface-area powders, and high-density semismooth particles. These powders exhibit uniform size and structure and high surface areas, and the method of production affords a high degree of purity with respect to other metallic elements.

Spikey particles are a general-purpose type of nickel powder (Inco type 123). They are fine and regular in shape, with rough surface projections (Fig. 2). The powder typically contains 700 to 900 mL/m³ (700 to 900 ppm) oxygen, 3 to 5 mL/m³ (3 to 5 ppm) iron, 1 mL/m³ (1 ppm) sulfur or less, and 600 to 700 mL/m³ (600 to 700 ppm) of graphitic carbon. The Fisher subsieve size is 3 to 7 μm, and apparent density is 1.8 to 2.7 g/cm³. Surface area is on the order of 0.4 m²/g (BET).

Fig. 2 Scanning electron micrograph of general-purpose nickel powder produced by carbonyl decomposition. 3000×

Filamentary nickel powders (Inco types 255, 287, etc.) are characterized by their unique, spikey, chainlike structure of relatively fine particles, which makes them fluffy in nature, with low apparent density (0.5 to 1.0 g/cm³) and large specific surface area (0.6 to 0.7 m²/g). The structure and asymmetrical filament shape of this powder type are illustrated in Fig. 3.

Fig. 3 Scanning electron micrograph of the filamentary-type nickel powder produced by carbonyl decomposition. 1000×

Extra fine nickel powders (e.g., Inco type 210) also have filamental morphology, but the filaments are finer and specific areas range from 1.5 to 6 m²/g depending on the grade.

Semi smooth high-density nickel powders are available in fine and coarse sizes. The fine is 10 to 20 μm in diameter (Fig. 4); the coarse is -16+40 mesh. Powder apparent density ranges from 3.5 to 4.2 g/cm³.

Fig. 4 Scanning electron micrograph of high-density (fine) nickel powder produced by carbonyl decomposition. 1000×

The properties of these high-purity nickel powders have been tailored to meet the demanding requirements of the chemical, energy, and metal industries. Currently, these products provide the basic nickel source for a wide range of specialized products. Application areas for these powders include:

- Batteries and fuel-cell electrodes
- P/M parts
- Ferrites
- Carbide cutting tools
- Catalysts
- Welding products
- Pigments and coatings
- Chemicals
- Electronic alloys
- Getters
- Conductive resins and plastics
- Electromagnetic shielding

Production of Nickel-Base Powders

Production of Nickel Powder by Hydrometallurgical Processing

Gavin Freeman, Sherritt International Corporation

The production of nickel powders by hydrometallurgical processing incorporates leaching, solution purification, and metal recovery operations. The Sherritt (Corefco) refinery in Fort Saskatchewan, Alberta, Canada, provides an example of hydrometallurgical processing used in the production of nickel powder. This refinery commenced operations in 1954, at which time the feedstock for the plant was nickel concentrate from Sherritt's Lynn Lake mining operations in Manitoba. The Sherritt refinery was the first successful commercialization of a hydrometallurgical process for the treatment of a nickel sulfide concentrate. The refinery has undergone process and equipment modifications in recent years to increase its capacity and enable the acceptance and treatment of different feedstocks. At present, the primary feed to the refinery is a high-grade nickel cobalt sulfide from Moa, Cuba.

A flow diagram of the Sherritt process is shown in Fig. 5. The Sherritt process is adaptable to handle a wide variety of different feedstocks. It has been adopted by Western Mining Corporation in a refinery at Kwinana, Western Australia. Further information regarding the Sherritt process is contained in Ref 4, 5, 6, 7, 8.

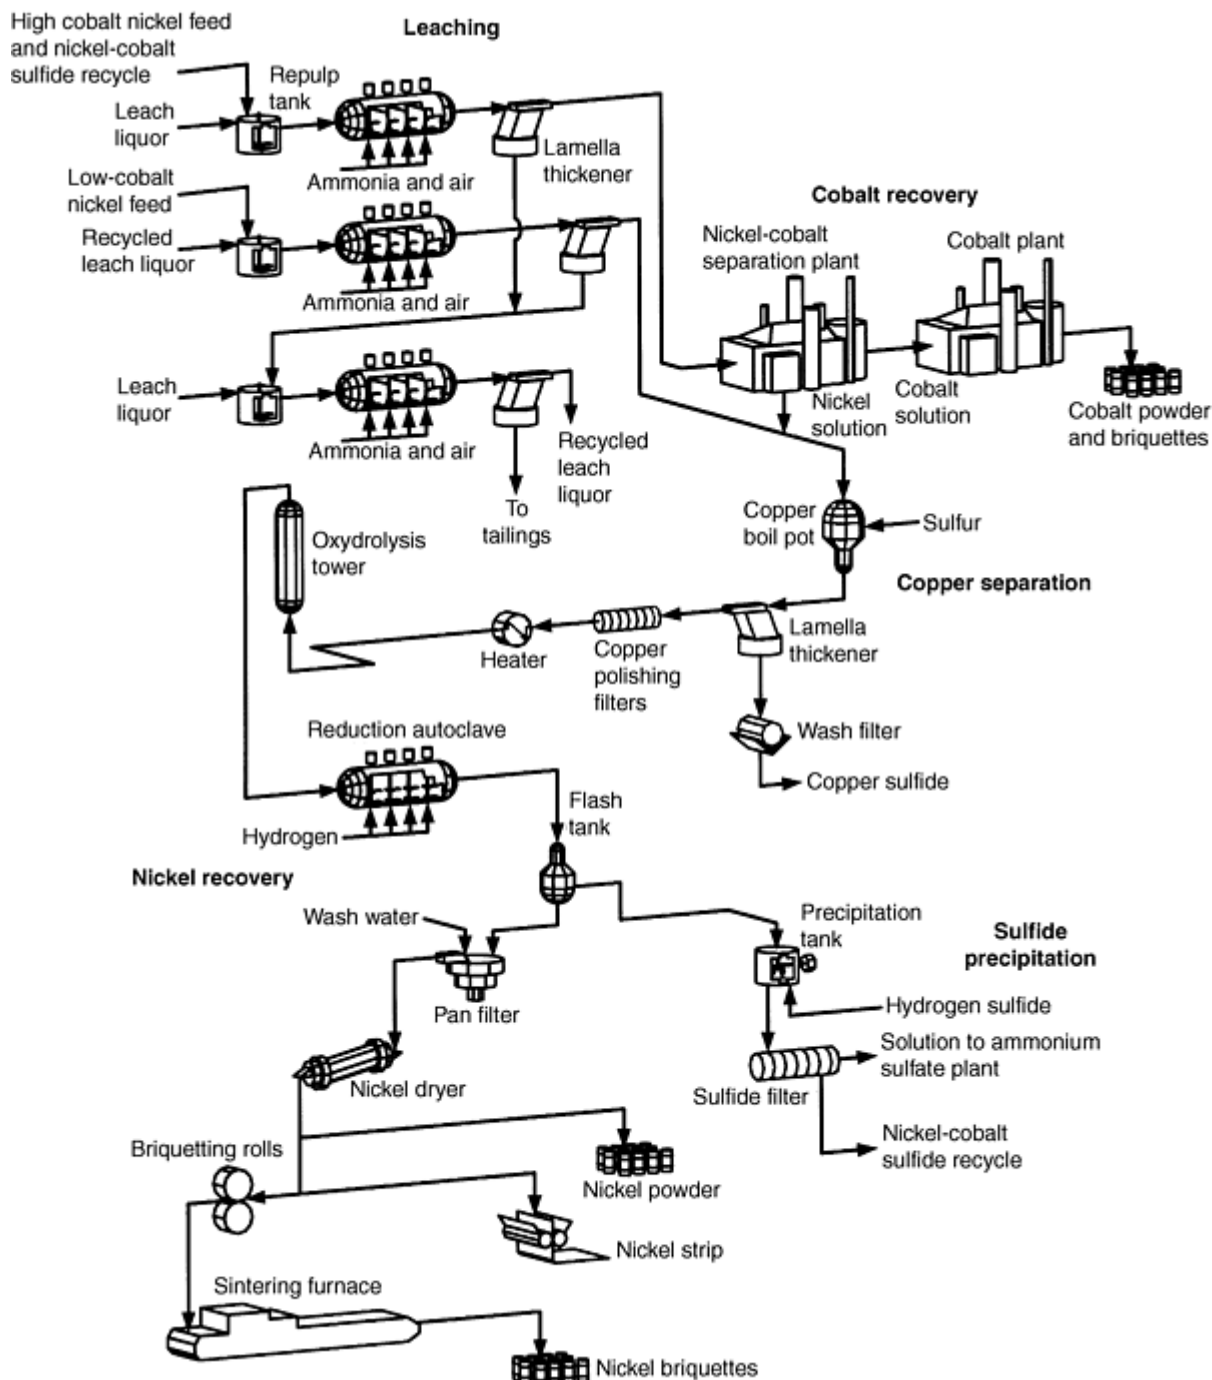

Fig. 5 Flowsheet of the Sherritt ammonia pressure leach process

Feed to Process. At present, the principal feed to the Sherritt refinery is a nickel and cobalt sulfide produced in Moa, Cuba. The Moa Bay lateritic deposits contain ore that is high in iron and also relatively rich in cobalt. The processing of this ore is accomplished through pressure leaching with sulfuric acid. The key step in this process is the separation of nickel and cobalt from iron. Iron, which typically constitutes 50% of the ore, is separated by precipitation at high temperature and pressure in an acid leaching step. It is possible to achieve the selective dissolution of nickel and cobalt with less than 1 g/L iron in the leach liquor. The leach liquor is neutralized using limestone mud, and the metal values in the leach liquor are then precipitated with hydrogen sulfide. The chemical analysis of the cobalt-nickel sulfide produced at Moa is given in Table 1. This material is packaged, as a wet filter cake, in bulk bags and transported to the refinery in Fort Saskatchewan. A schematic flowsheet for the Moa Bay process is shown in Fig. 6.

Table 1 Chemical composition of Moa sulfides

Component	Analysis, wt%
Nickel	51-56
Cobalt	5.0-6.0
Iron	0.5-0.8
Copper	0.1-0.2
Sulfur	32-37
Zinc	1.0-1.3

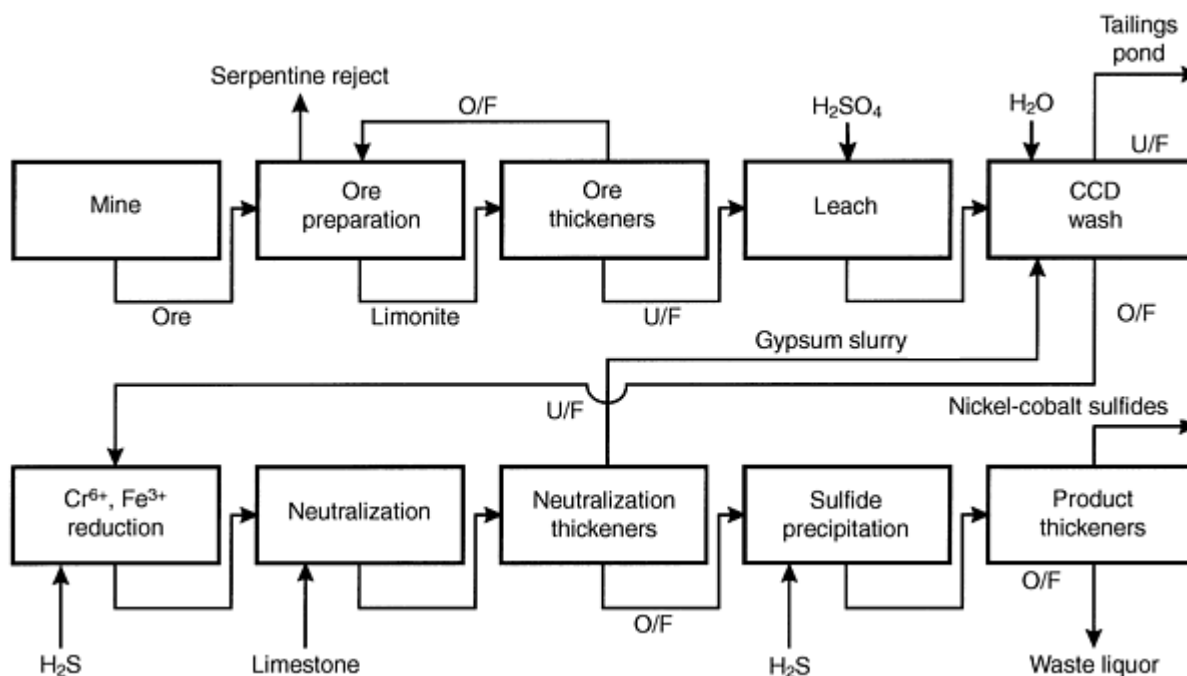

Fig. 6 Flowsheet for the Moa Bay process. O/F, thickener overflow; U/F, thickener underflow; CCD, counter current decantation

Leaching. At Fort Saskatchewan, the first stage in the refining process is the leaching of the metal values from the sulfide feeds into solution. The fine sulfide concentrate feed materials are blended with an ammonium sulfate leaching liquor in a repulp tank and are then fed into the leach autoclaves. In the leaching process, air, ammonia, and the sulfidic minerals react in a series of interrelated steps. The leaching process is carried out at elevated temperature and pressure in a continuous process. The typical conditions in the leach autoclaves are given in Table 2.

Table 2 Leaching conditions

Parameter	Value
Temperature, °C	90-95
Pressure, psig	110-120
Ammonia, g/L	80-110
Ammonium sulfate, g/L	150-200

The net leach reaction is the oxidative dissolution of the metal sulfides to soluble ammine complexes with the simultaneous oxidation of sulfide sulfur (S^{2-}) to form a series of soluble thio salts including sulfate (SO_4^{2-}). The general equation for the ammoniacal leaching of sulfides may be represented as:

where M = nickel, cobalt, iron, copper, zinc, and $n = 2$ to 6.

The leaching process takes advantage of the differing stability of the ammine complexes. The iron ammine complex is the least stable and is completely hydrolyzed to a hydrated iron oxide, $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (hematite), which is reprecipitated. The leach slurry passes to a lamella thickener where the leach liquor is separated from the solid residue.

In fact, the actual reaction chemistry of the leaching process is much more complex due to the behavior of sulfur in alkaline solutions. The reaction sequence of the oxidation of sulfur to form sulfate, sulfamate, and a range of ammonium thiosalts may be represented as follows:

where $n = 2$ to 6. At any given time, the leach liquor will contain sulfur in several forms. The amounts of these species present depend on the leach conditions and duration (Fig. 7.). The leach solution typically contains 60 to 70 g/L Ni, 6 to 9 g/L Co, 1 to 2 g/L Cu, 130 g/L NH_3 , 200 g/L $(\text{NH}_4)_2\text{SO}_4$, and varying amounts of other sulfur oxyanions.

Fig. 7 A representation of the leach solution composition as determined in batch leaching tests

Before it is possible to reduce the nickel from the leach solution as the pure metal, several solution purification steps must be completed.

Cobalt Separation. The leach liquor is transferred to the nickel-cobalt separation plant. Here cobalt is separated from the nickel as pure crystalline cobaltic hexammine salt. The Sherritt cobalt refining process is further discussed in the article "Production of Cobalt-Base Powders" in this Volume. After the removal of cobalt, the nickel-rich, or "pregnant," solution proceeds through the copper-removal circuit.

Copper Removal. Copper is removed from the leach liquors and pregnant solution from cobalt separation in a unit operation referred to as the "copper boil." In the copper boil, the combination of lowering the ammonia level by boiling to distill off the free ammonia and the addition of elemental sulfur and sulfur dioxide at elevated temperature results in the precipitation of copper sulfide. The copper is a mixture of cupric sulfide (CuS) and cuprous sulfide (Cu₂S) and is prepared by the reaction of soluble copper with thiosulfate ($S_2O_3^{2-}$):

The selectivity for copper is achieved by the fact that copper sulfide is less soluble than nickel sulfide. This copper sulfide by-product is filtered, washed, and then sold to a copper smelter.

Oxidation and Hydrolysis. The solution remaining after copper removal contains appreciable amounts of sulfamate ($SO_3NH_2^-$) and other forms of unsaturated sulfur. The removal of all unsaturated sulfur compounds is necessary before the nickel can be recovered. If these sulfur compounds are not fully converted to sulfate, the nickel powder product would contain unacceptably high levels of sulfur. These are removed by hydrolyzing the sulfamate to sulfate at 245 °C (473 °F) and oxidizing the thionates to sulfate with air at 4800 kPa (700 psi) in one combined step referred to as "oxyhydrolysis." The major reactions taking place in oxyhydrolysis are:

Ammonium sulfamate is a herbicide and must be hydrolyzed to sulfate to avoid contamination of the ammonium sulfate fertilizer. Ammonium sulfate is crystallized from the reduction end solution, following sulfide precipitation of the minor amounts of metal remaining in solution after hydrogen reduction.

Metal Recovery. In the final step of the Sherritt process, nickel is precipitated from solution as a metal powder through a process referred to as hydrogen reduction. The objective of the hydrogen reduction process is to precipitate the nickel ions present in the purified solution to nickel powder using hydrogen gas as a reductant. The reduction of metals from solution by hydrogen requires that the hydrogen potential of the system should exceed the electrode potential of the metal ions, in which case hydrogen will go into solution and the metal precipitates. The hydrogen potential is governed by the pH of the solution and by the partial pressure of hydrogen applied as shown in Fig. 8. The electrode potential of the metal ions is, however, little affected by concentration.

Fig. 8 Hydrogen and metal electrode potentials in solution

The reduction process is carried out in mechanically agitated horizontal autoclaves at elevated temperatures and pressures. This is a batch process consisting of two distinct stages, initial nucleation, and subsequent densifications. In the initial nucleation stage, fine nickel seed powder is formed in the autoclave. The densification refers to the process whereby nickel from solution is reduced onto the seed powder, which then grows in size. The reduction process, where 1 mole of hydrogen reduces 1 mole of nickelous ions to metallic nickel and yields 2 moles of ammonium ions as by-product, can be written:

The presence of free ammonia is necessary to neutralize the hydrogen ions produced during reduction. At low pH and lower hydrogen potentials the reduction of the metal ions effectively ceases. During the reduction process, the slurry in the autoclave is agitated by impellers; however, once reduction is complete the agitation is stopped and the nickel powder is allowed to settle. The spent solution (or reduction end solution) is then pumped out and the autoclave is filled with fresh nickel solution, the agitators are restarted and hydrogen pressure is applied. This batch reduction process is repeated 50 to 60 times to build up consecutive coatings of nickel on the powder particles. The overall process is stopped when the powder has reached the desired size. During the final discharge, the agitators are kept running and the entire contents of the autoclave are pumped to the flash tank.

In addition to nickel, the feed solution to reduction also contains significant quantities of cobalt and zinc. Zinc does not present a problem with respect to contamination of the product powder, because zinc will not be reduced to the metallic state under the conditions employed. Cobalt on the other hand has a similar standard reduction potential to that of nickel

(-0.267 V for cobalt compared to -0.241 V for nickel). In order to effect the preferential reduction of nickel, the ammonia concentration is adjusted in the nickel reduction feed solution to give a NH_3 -to-total metals molar ratio of 1.9 to 1.

In practice, the reduction feed solution contains 65 g/L Ni, 2.5 g/L Co, and 2 g/L Zn. The reduction of nickel ions to metal occurs rapidly only as a heterogeneous reaction, in which nickel is precipitated onto an existing surface. Figure 9 shows the change of particle size and apparent density with the number of reduction cycles or densifications. Figure 10 shows a scanning electron micrograph of a Sherritt produced nickel powder. The analysis of Sherritt's standard grade nickel powder is given in Table 3.

Fig. 9 Physical characteristics of nickel powder produced in a commercial operation

Fig. 10 Scanning electron micrograph (1000×) of nickel powder

The addition of various organic additives to the densification reductions can also be used to provide the means of controlling the size, shape, and surface morphology of the powder produced.

The slurry of powder and reduction end solution is discharged from the autoclave and collected in flash tanks. The solution is allowed to overflow into a holding tank and is then pumped to sulfide precipitation. The nickel powder is then drawn off from the flash tank cone as a 90% solids slurry and is filtered and washed on a rotary pan filter. From the pan filter the wet powder (typically 5% moisture) is fed by a screw feeder into a gas-fired rotary dryer.

The dried-and-cooled nickel powder is either packaged as a powder product, or it can be directed to the briquetting operation. For briquetting, the nickel powder is first blended with an organic binder in a pug mill and is then compressed using a roll-briquette device. The briquettes are fed through a sintering furnace to effect carbon and sulfur removal and, through sintering at high temperature, impart structural integrity to the briquettes. The removal of carbon from the briquettes relies on the oxidation of carbon and its release as either CO or CO₂. In contrast to this, the mechanism for sulfur removal depends on the maintenance of reductive conditions through hydrogen injection, with the release of H₂S. The sintering furnace therefore consists of three distinct zones: the oxidizing "preheat zone" for carbon removal, the reducing "hot zone" for sulfur removal, and finally a "cooling zone." After exiting the furnace, the briquettes are packaged as the finished product (Fig. 11).

Fig. 11 Nickel briquettes (each briquette is ~38 by 25 by 18 mm, or 1.5 by 1.0 by 0.7 in.)

Sulfide Precipitation. The liquor from hydrogen reduction contains residual nickel, cobalt, and zinc. These metal ions are precipitated using hydrogen sulfide and recovered as sulfide precipitates. The general precipitation reaction is:

where M = nickel, cobalt, zinc. Metals can be selectively removed from solution by controlling pH of the sulfide precipitation reaction. The pH is controlled by the addition of ammonia to neutralize the acid generated in the precipitation reaction:

The nickel and cobalt sulfides are then returned to the leach, the zinc sulfide (which is precipitated independently of nickel and cobalt sulfide) is sold as a by-product, and the barren liquor (metal free ammonium sulfate solution) proceeds to ammonium sulfate recovery.

Ammonium Sulfate Recovery. The solution obtained after removal of the metal values as metal sulfides, contains only ammonium sulfate. This solution, referred to as "barren solution" is then evaporated and ammonium sulfate, which is formed as an overall refinery by-product, is recovered in a crystalline form. The ammonium sulfate recovery consists of crystallization followed by centrifuging, drying, and screening. The crystalline ammonium sulfate is then sold as a fertilizer.

Applications. Most hydrometallurgically produced nickel powder is compacted into briquettes or rondelles for consumption as an alloying additive in the steel industry. Smaller amounts of powder are roll compacted into nickel strip or dissolved to produce various nickel salts.

Production of Nickel-Base Powders

Atomization

K.M. Kulkarni, *Advanced Metalworking Practices*, Inc.

Atomized nickel-base alloy powders are used primarily for hardfacing or aerospace components. Materials for hardfacing processes include various types of hardfacing processes, equipment, materials, and types of applications that are described in greater detail in the article "Welding and Hardfacing Powders" in this Volume. Atomized nickel-base powders are also described below with additional information in the article "Powder Metallurgy Superalloys."

Nickel-base hardfacing powders are produced by gas and water atomization. Unlike other alloy systems, nickel-base hardfacing powders are predominantly spherical in shape, even when produced by water atomization. Oxygen content is somewhat higher than gas-atomized powders, but is still below 1000 mL/m³ (1000 ppm). Generally, melting practice and control during each manufacturing step affect product quality more than the atomization process.

Most nickel-base hardfacing powders are of the Ni-Cr-B-Si type and are self-fluxing during deposition because of the presence of boron and silicon. These elements also influence the melting temperature range of any specific alloy; melting range is an important factor for hardfacing powders. Table 4 gives typical compositions of several common grades.

Table 4 Compositions and melting ranges of typical nickel-base hardfacing alloys

Nominal Composition	Melting range		Deposit hardness, HRC
	°C	°F	
1.5B-2.8Si-Ni	940-1260	1725-2300	19-24
1.7B-0.35C-7.5Cr-3.5Si-Ni	994-1152	1820-2105	35-42
2.4B-0.45C-11Cr-4Si-Ni	976-1063	1790-1945	49-52

The industrial use of Ni-B-Si and Ni-Cr-B-Si alloys for thermally sprayed and subsequently fused coatings developed beginning around 1955. During the period 1956 to 1960, most of these metal powders were produced by crushing processes; however, since about 1960 atomization from a melt became more widely utilized. Most of the atomization installations for these types of alloys utilized high-pressure water atomization as was also used for the production of powders.

The influence of cooling rate during atomization can have important effects on the metallurgical structure of the powders and on their behavior during thermal spraying. For example, there is a clear tendency toward the presence of unstable intermetallic nickel-boron compounds, such as Ni_3B_4 and Ni_4B_3 , with increased atomization cooling rates (Ref 9). The quantity of these unstable phases has an influence on the self-fluxing reactions and on the wetting properties during fusing. This is due to the much higher velocity of the reaction of these unstable phases with the oxides present on the base metal surface. For these phases this velocity is estimated to be more than twice that for the more stable phase, NiB.

When chromium boride particles are present (i.e., from a lower atomization cooling rate), they have little influence on wetting during fusing. An increase in the content of stable phases (such as Cr_2B or CrB) increases hardener stability and ductility because less boron is used for the self-fluxing reaction. The crack resistance during bending also is distinctly improved for coatings produced with lower-cooling-rate powders.

The final boron content of the fused coatings produced with rapidly cooled powders may be up to 0.2% less than for the coatings produced with slower-cooled powders. The overall finer structure produced with more rapidly cooled powders also provides improved resistance to wear in the final coating. These same features are expected to contribute to improved corrosion resistance.

Superalloy Powders (Adapted from Ref 10). In aerospace applications, several P/M superalloys have replaced forged turbine disk alloys. The P/M alloys are characterized by a high homogeneous concentration of both solid-solution strengthening elements and the γ' -forming elements aluminum and titanium. These factors would limit forgeability of conventionally cast and wrought alloys. Compositions are listed in Table 5.

Table 5 Chemical compositions of some nickel-base superalloys produced by powder metallurgy

Various means of producing superalloy powders are summarized in Table 6. Inert gas atomization is the most common technique. An ingot is first cast, typically by vacuum induction melting, in order to minimize oxygen and nitrogen contents. In some cases remelting may be carried out by electron beam heating, arc melting under argon, or plasma heating. Atomization is carried out by pouring master melt through a refractory orifice; a high-pressure inert gas stream (typically argon) breaks up the alloy into liquid droplets, which are solidified at a rate of about 10^2 K/s.

Table 6 Powder production methods

Step	Inert gas atomization ^(a)	Soluble gas process	Rotating electrode process ^(b)	Plasma rotating electrode process	Centrifugal atomization with forced convective cooling (RSR) ^(c)
Melting 1	VIM; ceramic crucible	VIM; ceramic crucible	VIM, VAR, ESR	VIM, VAR, ESR	VIM; ceramic crucible
Melting 2	Argon arc	Plasma	...
Melt disintegration system/environment	Nozzle; argon stream	Expansion of dissolved hydrogen against vacuum and Ar + H ₂ mixture	Rotating consumable electrode; argon or helium	Rotating consumable electrode; argon	Rotating disk; forced helium convective cooling

Source: Ref 11

- (a) VIM, vacuum induction melting.
 (b) VAR, vacuum arc remelting; ESR, electroslag remelting.
 (c) RSR, rapid solidification rate.

The spherical powder is collected at the outlet of the atomization chamber. The maximum particle diameter resulting from this process depends on the surface tension, γ , viscosity, η , and density, ρ , of the melt, as well as the velocity, ν , of the atomizing gas. The principal factor is gas velocity. Oxygen contents are of the order of 100 ppm, depending on particle size. Finer particle sizes are obtained by screening.

Another important powder production method, the soluble gas process, is based on the rapid expansion of gas-saturated molten metal, resulting in a fine spray of molten droplets that form as the dissolved gas, usually hydrogen, is suddenly released (Fig. 12, Ref 12). The droplets solidify at a rate of about 10^3 K/s, and the cooled powder is collected under vacuum in another chamber, which is sealed and backfilled with an inert gas. This method is capable of atomizing up to 1000 kg (2200 lb) of superalloy in one heat and produces spherical powder that can be made very fine. This method has been successfully employed for LC Astroloy, MERL 76, and IN-100.

Fig. 12 Soluble gas atomization system for producing superalloy powder. Source: Ref 12

The third method of powder preparation is based on centrifugal atomization. The melt is accelerated and disintegrated by rotating under vacuum or in a protective atmosphere. One example of this method is the rotating electrode process (REP) used in the early production of IN-100 and René 95 powder. In this process, a bar of the desired composition, 15 to 75 mm (0.6 to 3 in.) in diameter, serves as a consumable electrode. The face of this positive electrode, which is rotated at high speed, is melted by a direct current electric arc between the consumable electrode and a stationary tungsten negative electrode. The process is carried out in helium. Centrifugal force causes spherical molten droplets to fly off the rotating electrode. These droplets freeze and are collected at the bottom of the tank, which is filled with helium or argon. A major advantage of this process is the elimination of ceramic inclusions and the lack of any increase in the gas content of the powder relative to the alloy electrode.

A variant on the REP process is the plasma rotating electrode process (PREP). Instead of a tungsten electrode, a plasma arc is used to melt the superalloy electrode surface. Cooling rates are higher, up to 10^5 K/s for IN-100 powder. On average, particle sizes are nearly twice as large in these processes as in gas atomization. More information on the REP process is described in the article "Rotating Electrode Process" in this Volume.

When solidification rates of powder exceed 10^5 K/s, the process is referred to as rapid solidification rate (RSR). For superalloys, the objective of the high rates is to obtain a microcrystalline alloy rather than an amorphous material. Apart from extremely fine grain size, such powders display nonequilibrium solubilities and very uniform compositions because of the very fine dendritic arm spacings resulting from rapid solidification. Both conventional superalloys and new alloys based on Ni-Al-Mo-X alloys, where X = tantalum or tungsten, have been prepared by RSR.

Rapid solidification processing can be done by centrifugal atomization with forced convective cooling. In this method, the alloy is vacuum induction melted in the upper part of a chamber. The chamber is then backfilled with helium, and the alloy is poured in a preheated tundish. The liquid is poured through the tundish nozzle onto a rotor that is spun at 24,000 rev/mm. The melt is accelerated to rim speed and then ejected longitudinally as droplets. Further atomization and cooling

of the droplets is accomplished by the injection of helium gas through annular nozzles. Spherical powder in the 10 to 100 μm (400 to 4000 $\mu\text{in.}$) diam range is produced; the cooling rate typically varies between 10^5 and 10^7 K/s, the higher rates being achieved with the smaller particles.

Rapidly solidified powders can also be prepared from melt spun ribbon that is pulverized after solidification. The ribbon is produced by pouring the melt through an orifice under pressure and impinging it on a rotating wheel of, for example, copper, that acts as a heat sink. Typical cooling rates are approximately 10^6 K/s, and ribbon thicknesses are less than 25 μm (1000 $\mu\text{in.}$). The ribbon must be mechanically pulverized, and this method is generally limited to small quantities of experimental alloys.

Production of Nickel-Base Powders

Mechanical Alloying*

Mechanical alloying (MA) was originally developed for the manufacture of nickel-base superalloys strengthened by both an oxide dispersion and γ' precipitate. Now in its third decade of advancement since the first work of Benjamin (Ref 15), MA provides a means for producing a full range of complex dispersion-strengthened nickel-, cobalt-, iron-, titanium-, and aluminum-base powder systems.

Mechanical alloying is a dry, high-energy ball-milling process for producing composite metallic powders with a controlled, fine microstructure. It is carried out in a highly agitated ball charge by repeated cold welding and fracturing (Fig. 13) of a mixture of metal powders to which some nonmetal powders may be added. Its widest use has been in the production of dispersion-strengthened nickel- and iron-base superalloys for service at temperatures of 1000 $^{\circ}\text{C}$ (1830 $^{\circ}\text{F}$) and above.

Fig. 13 Ball-powder-ball collision of powder mixture during mechanical alloying. (a) Cold welding. (b) Powder fracture. Courtesy of International Nickel Co., Inc.

Unlike mechanical mixing processes, mechanical alloying produces a material whose internal homogeneity is independent of starting powder particle size. Thus, ultrafine dispersions (less than 1 μm interparticle spacing) can be obtained with relatively coarse initial powder (50 to 100 μm average diameter).

Equipment. The machinery used for mechanical alloying consists of one of several types of high-energy ball mills. These are selected on the basis of given processing times, ranging from hours to tens of hours. The types of ball mills employed include shaker mills, vibratory mills, stirred ball mills, centrifugal ball mills, and conventional ball mills with diameters greater than about 1 m. The restriction on conventional ball mills arises from the relatively low-energy density of operation of smaller mills, which leads to excessive processing times.

Unlike the procedure used in ball milling for comminution, the ratio of balls to powder in mechanical alloying is relatively high. These ratios range from 6:1 by weight to as high as 30:1, but most commonly are in the range of 10:1 to 20:1. The balls themselves range from 4 to 20 mm (0.16 to 0.8 in.) in diameter, but are usually 8 to 10 mm (0.32 to 0.4 in.) in diameter and are made of a through-hardened steel, such as 52100. The environment within the grinding machine is controlled wherever practical; water cooling and atmosphere control are employed. The milling atmosphere consists of either nitrogen or argon with measured trace amounts of oxygen. Liquids can also be used.

Production of Oxide-Dispersion-Strengthened (ODS) Superalloy Powders. The raw materials used for mechanically alloyed dispersion-strengthened superalloys are widely available commercially pure powders that have particle sizes that vary from about 1 to 200 μm . These powders fall into the broad categories of pure metals, master alloys, and refractory compounds. The pure metals include nickel, chromium, iron, cobalt, tungsten, molybdenum, and niobium. The master alloys include nickel-base alloys with relatively large amounts of combinations of aluminum, titanium, zirconium, or hafnium.

These master alloys are relatively brittle when cast and easily comminuted to powder. In addition, because they consist of relatively exothermic intermetallic compounds, the thermodynamic activity of the reactive alloying elements, such as aluminum and titanium, is considerably reduced compared to that of the pure metals.

A typical powder mixture may consist of fine (4 to 7 μm) nickel powder, -150 μm chromium, and -150 μm master alloy. The master alloy may contain a wide range of elements selected for their roles as alloying constituents or for gettering of contaminants. About 2 vol% of very fine yttria, Y_2O_3 (25 nm, or 250 \AA) is added to form the dispersoid. The yttria becomes entrapped along the weld interfaces between fragments in the composite metal powders. After completion of the powder milling, a uniform interparticle spacing of about 0.5 μm (20 $\mu\text{in.}$) is achieved.

The oxygen contents of the commercially pure metal powders and the master alloys range from 0.05 to 0.2 wt%. The refractory compounds that can be added include carbides, nitrides, and oxides. For the production of dispersion-strengthened materials, such additions are limited to very stable oxides, such as yttria, alumina, or less frequently thoria. These oxides, which are prepared by calcination of oxalate precipitates, consist of crystallites of about 50 nm agglomerated into pseudomorphs of about 1 μm .

The only restriction on the mixture of powder particles for mechanical alloying (other than the particle size range mentioned above and the need to minimize excessive oxygen) is that at least 15 vol% of the mix should consist of a compressibly deformable metal powder. The function of this component, which can consist of any one or all of the pure metals, is to act as a host or binder for the other constituents during the process.

Other similar metals, such as copper, zinc, and magnesium, are suitably ductile but not normally added to superalloys. For dispersion-strengthened superalloys, the amount of refractory oxide added ranges from about 0.4 to 1.5 wt% (1 to 2.7 vol% for yttria).

Powder Characteristics. A uniform distribution of submicron refractory oxide particles must be developed in a highly alloyed matrix for the production of ODS alloys. A given sample of mechanically alloyed superalloy powder may contain particles ranging from 10 to 500 μm , with an average particle size between 50 and 200 μm . The internal structure of the powder is independent of particle size once the steady state is achieved.

Because of the severe plastic deformation that occurs during mechanical alloying, very high hardnesses are achieved in the powders. Hardness increases almost linearly during the initial stages of the process (Fig. 14), reaching a saturation value, after which time it is presumed that work softening balances further cold work.

Fig. 14 Change of hardness and magnetic response during mechanical alloying. Courtesy of International Nickel Co., Inc.

It has also been noted by magnetic measurements (Fig. 14) that true alloying occurs, as evidenced by the loss of saturation magnetic moment, with increasing processing time in a high-nickel composition. This may be due to a combination of factors. First, the extreme amount of cold work leads to low activation energy and pipe diffusion. Second, the temperature is moderately elevated to approximately 150 °C (300 °F) during the process. Third, relatively short interdiffusion distances (less than 1 μm) exist toward the end of the process.

Commercial Alloys. The most common mechanically alloyed ODS alloys include MA 754, MA 758, MA 956, MA 6000, and MA 760.

Alloy MA 754 was the first mechanically alloyed ODS superalloy to be produced on a large scale. This material is basically a Ni-20Cr alloy strengthened by about 1 vol% Y_2O_3 (see Table 7). It is comparable to TD NiCr (an earlier ODS material strengthened by thorium, ThO_2) but has a nonradioactive dispersoid, and because of its higher strength, has been extensively used for aircraft gas-turbine vanes and high-temperature test fixtures.

Table 7 Nominal composition of selected mechanically alloyed materials

Alloy designation	Composition, %											
	Cr	Al	Ti	W	Mo	Ta	Y_2O_3	C	B	Zr	Ni	Fe
MA 754	20	0.3	0.5	0.6	0.05	bal	...
MA 758	30	0.3	0.5	0.6	0.05	bal	...
MA 760	20	6.0	...	3.5	2.0	...	0.95	0.05	0.01	0.15	bal	...
MA 6000	15	4.5	2.5	4.0	2.0	2.0	1.1	0.05	0.01	0.15	bal	...
MA 956	20	4.5	0.5	0.5	0.05	bal

Alloy MA 758 is a higher-chromium version of MA 754 (see Table 7). This alloy was developed for applications in which the higher chromium content is needed for greater oxidation resistance. The mechanical properties of this alloy are similar to those of MA 754 when identical product forms and grain structures are compared. This alloy has found applications in the thermal processing industry and is also used in the glass-processing industry.

Alloy MA 956. The production of alloy MA 956 demonstrates the ability to add large amounts of metallic aluminum by mechanical alloying (see Table 7). This material is a ferritic Fe-Cr-Al alloy, dispersion-strengthened with yttrium aluminates formed by the addition of about 1 vol% of yttria. Because of its generally good hot and cold fabricability, MA 956 has been produced in the widest range of product forms of any MA ODS alloy. In sheet form, this alloy is produced by a sequence of hot and cold working, which yields large pancake-shape grains following heat treatment. This grain structure ensures excellent isotropic properties in the plane of the sheet. MA 956 is used in the heat treatment industry for

furnace fixturing, racks, baskets, and burner nozzles. It also is used in advanced aerospace sheet and bar components, where good oxidation and sulfidation resistance are required in addition to high-temperature strength properties.

Alloy MA 956 has a very high melting point (1480 °C, or 2700 °F), a relatively low density (7.2 g/cm³) compared to competitive materials, and a relatively low thermal expansion coefficient (see Table 8). This combination of properties makes the alloy well suited for sheet applications such as gas-turbine combustion chambers.

Table 8 Physical properties of selected mechanical alloying ODS materials

Alloy	Melting point		Modulus of elasticity		Mass density, g/cm ³	Coefficient of expansion, at 20 to 980 °C (70 to 1800 °F)	
	°C	°F	GPa	10 ⁶ psi		μm/m · K	μin./in. · °F
MA 754	1400	2550	151	22	8.3	16.9	9.41
MA 956	1480	2700	269	39.0	7.2	14.8	8.22
MA 6000	1296-1375	2365-2507	203	29.4	8.11	16.7	9.3

Alloy MA 6000 has a composition based on an alloy-development philosophy similar to that of the more sophisticated cast and wrought superalloys. This is because it contains a critical balance of elements to produce strength at intermediate and elevated temperatures, along with oxidation and hot-corrosion resistance. Alloy MA 6000 combines γ' hardening from its aluminum, titanium, and tantalum content for intermediate strength, with ODS from the yttria addition for strength and stability at very high temperatures. Oxidation resistance comes from its aluminum and chromium contents, while titanium, tantalum, chromium, and tungsten act in concert to provide sulfidation resistance. The tungsten and molybdenum also act as solid-solution strengtheners in this alloy. MA 6000 is an ideal alloy for gas-turbine vanes and blades where exceptional high-temperature strength is required.

Alloy MA 760 is an age-hardened nickel-base alloy with a composition designed to provide a balance of high-temperature strength, long-term structural stability, and oxidation resistance. Its primary use is expected to be for industrial gas turbines. The composition of this alloy is shown in Table 7. It is similar to MA 6000 in that its strength is supplemented by γ' age hardening. Its properties also benefit from zone annealing to give coarse elongated grains. The stress-rupture properties of alloy MA 760 exceed those of MA 754 but are exceeded by those of MA 6000 (see the article "Powder Metallurgy Superalloys" in this Volume).

Production of Cobalt-Base Powders

Gavin Freeman, Sherritt International Corp.

Introduction

COBALT POWDER is used primarily in the P/M industry as an alloying element in the production of permanent magnets, superalloys (high-temperature, creep-resistant alloys), wear-resistant hardfacing alloys, tool and die steels, and as a binder in cemented carbides. Approximately 60% of the world production of cobalt originates in Zaire and Zambia.

Cobalt is an important material to the P/M industry due to its ability to enhance the high-temperature properties of superalloys, the cutting ability of sintered carbide and high-speed tool steels, and the toughness of high-strength steels. This article discusses the three methods of cobalt powder production: hydrometallurgical processing, reduction of oxides, and atomization. Additional references are found at the end of this article.

Production of Cobalt-Base Powders

Gavin Freeman, Sherritt International Corp.

Hydrometallurgical Processing

The hydrometallurgical processing of cobalt includes three main processing steps: chemical dissolution (leaching), solution purification, and metal recovery. The production of cobalt powder at the Sherritt (Corefco) refinery in Fort Saskatchewan, Alberta, Canada, currently amounts to ~ 2400 tonnes of cobalt per year, representing roughly 10% of the world's supply. In addition, this process is an integral part of the solution purification steps of the nickel refining process as the same feedstock to the plant contains both nickel and cobalt values. A flow diagram of this process is shown in Fig. 1. More information on the process is contained in Ref 1, 2, and 3.

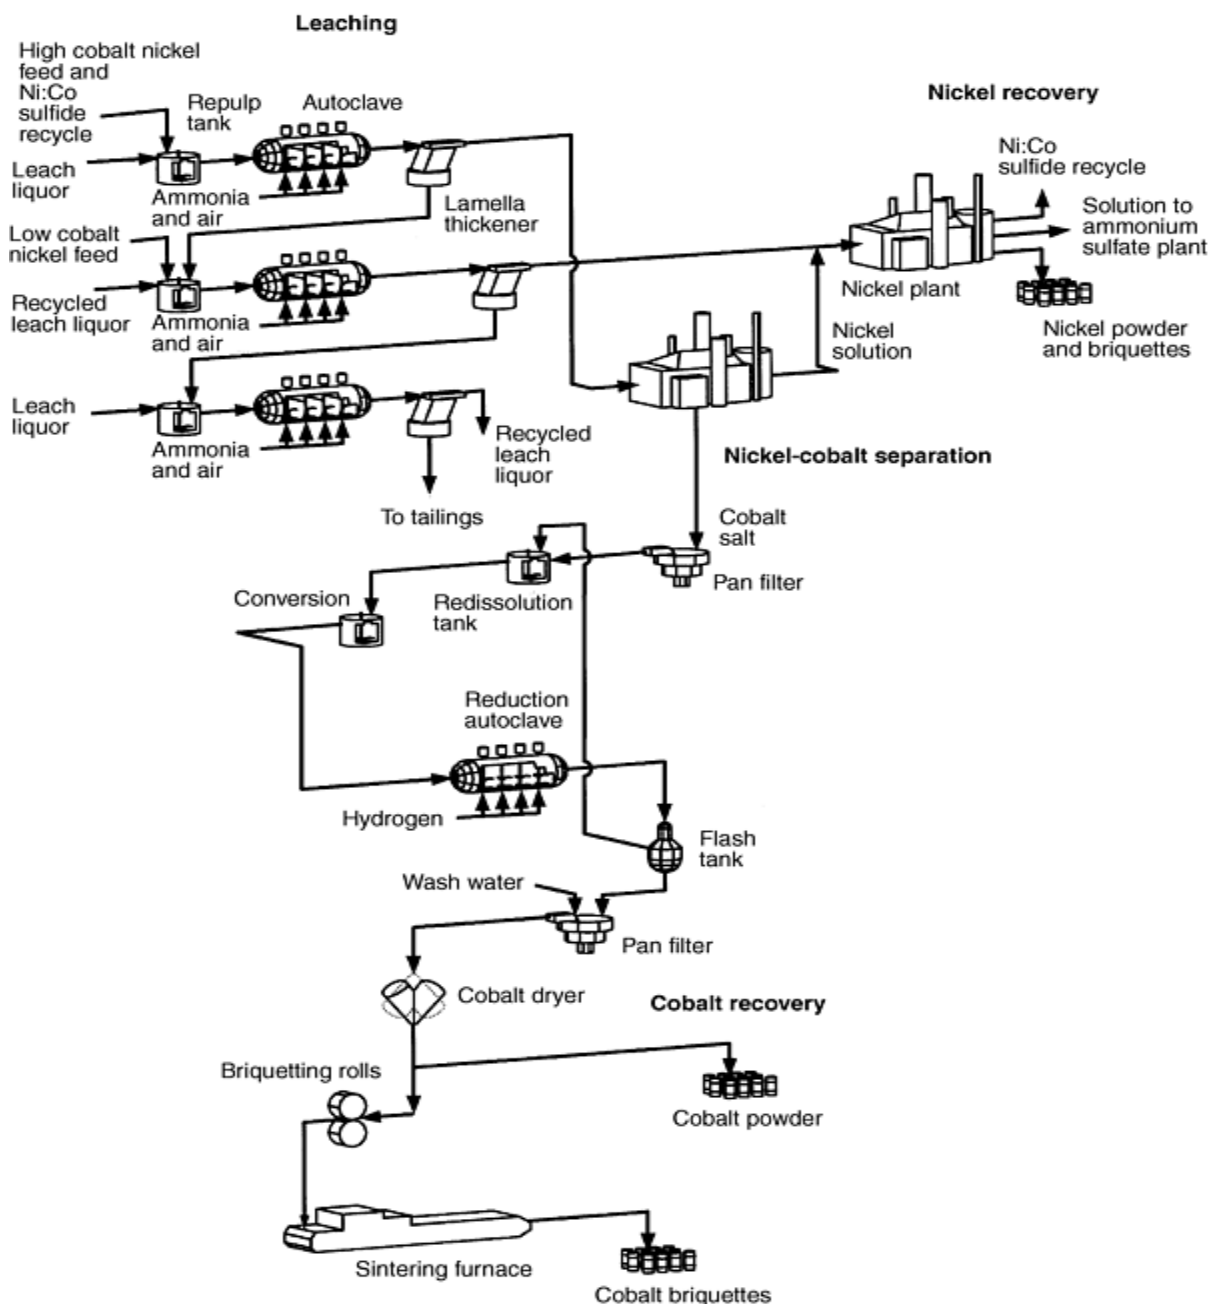

Fig. 1 Flowchart of the Sherritt cobalt refining process

Leaching. The production of cobalt at the Sherritt International refinery begins with the leaching of a mixed nickel and cobalt sulfide obtained from Moa, Cuba. The leaching process is based on the ammoniacal pressure leaching of the sulfides to produce soluble nickel and cobalt hexammine sulfate complexes. The details of the leaching process are outlined in the article "Production of Nickel-Base Powders" in this Volume.

The hexammine leach solution contains a variety of metal ammine sulfate complexes. Leaching conditions are carefully controlled to maximize the formation of the cobaltic hexammine complex. This is crucial as the efficiency of the subsequent cobalt separation depends on the fact that cobalt exists primarily as the hexammine complex in the leach solution.

The leach solution is then transferred to the cobalt separation plant, where cobalt is separated as a pure crystalline cobaltic hexammine salt. The nickel rich solution remaining after the selective removal of cobalt is directed to the nickel plant for further solution purification steps and ultimately nickel powder production.

Nickel-Cobalt Separation. The basis for the separation of cobalt from nickel is the separation and purification of cobalt (III) hexammine sulfate, $[\text{Co}(\text{NH}_3)_6]_2(\text{SO}_4)_3$. The initial step of this separation involves the precipitation of a cobalt-nickel hexammine salt. This precipitation is effected by the addition of ammonium sulfate and ammonia to the leach solution as shown in the following reaction:

The cobalt-nickel salt is then dissolved in water, followed by precipitation of the relatively insoluble cobaltic hexammine sulfate, while the more soluble nickel hexammine sulfate remains in solution. This selective nickel removal from the cobalt-nickel hexammine salt results in the isolation of a purified cobalt salt.

The cobalt hexammine salt is then recrystallized to further remove any nickel contamination. After washing and filtration, the pure cobalt salt is redissolved in an ammonium sulfate solution.

Cobalt Recovery. Reduction of the cobalt (III) present in the pure cobaltic hexammine solution to cobalt (II) is completed in a step referred to as "conversion." The conversion of cobaltic hexammine to a cobaltous ammine is a disproportionation reaction, and it is accomplished by the controlled addition of metallic cobalt as defined by the following stoichiometry:

Sulfuric acid is added to neutralize the free ammonia and maintain the molar ratio of ammonia to cobalt at approximately 2.3 to 1.

After conversion and adjustment of the ammonia concentration, this solution is suitable to be fed to the reduction autoclaves. The objective of the reduction process is the chemical reduction of cobaltous ammine to cobalt powder. The reduction of cobalt is a batch operation that occurs in a reduction autoclave under hydrogen atmosphere at elevated temperature and pressure.

Cobalt powder is produced in a cycle comprising one nucleation reduction, in which fine cobalt powder of sufficient surface area to function as catalyst is prepared, and up to 60 densifications. Nucleation reduction refers to the hydrogen reduction process by which fine cobalt seed powder is produced with the aid of a sodium sulfide/sodium cyanide catalyst. At the completion of the nucleation reduction, the solution is decanted from the seed powder, which remains in the autoclave to act as a catalyst during subsequent densification operations. In the course of a cycle, the originally fine seed powder coarsens or becomes densified.

The purpose of the densification reduction is to deposit reduced cobalt onto a seed particle until desired powder density, chemical composition, and screen fraction have been achieved. Each densification is a hydrogen reduction operation in which the autoclave is filled with the purified cobaltous solution, and hydrogen is added under pressure. Metallic cobalt then precipitates from solution depositing on the seed powder, by the following reaction:

The rate of the reduction reaction and its completeness depend on several factors including the ammonium sulfate concentration, the ratio of ammonia to cobalt, temperature, the hydrogen partial pressure, and the amount of seed material present. At the end of each densification, the powder is settled, the spent solution is decanted, and a fresh charge of cobaltous solution is introduced.

The slurry is then discharged from the autoclave to a flash tank where the initial separation of cobalt powder from the end solution is accomplished. The cobalt powder is transferred from the flash tank to a vacuum pan filter. After the cobalt is washed to remove ammonium sulfate, and dried, the product is packaged as powder or compacted into briquettes and sintered. Typical analysis of the Sherritt cobalt powder is given in Table 1.

Production of Cobalt-Base Powders

Gavin Freeman, Sherritt International Corp.

Thermal Decomposition of Cobalt Oxide

One of the major applications of cobalt powder is its use as a binder in the production of cemented carbides. Most of this powder is produced by the reduction of cobalt oxide with hydrogen at relatively low temperatures, generally below 800 °C (1470 °F) to obtain the necessary degree of fineness.

Powder grades used in cemented carbides should pass through 325 mesh. Small particle sizes are required, because the cobalt powder must be intimately mixed with tungsten carbide particles by ball milling. Typical properties of reduced cobalt powders are the following:

Atomization

Atomized powders of cobalt-base alloys find wide usage in high-temperature applications, although this section discusses only hardfacing powders. Cobalt-base alloys for hardfacing applications typically are the cobalt-chromium-tungsten-nickel-carbon types. These powders are gas atomized to minimize oxygen pickup.

Some manufacturers prefer vacuum melting and inert-gas atomization over air melting followed by inert-gas (typically nitrogen or argon) atomization. Oxygen content in these atomized powders is significantly <1000 ppm, although the nitrogen level may vary from 600 to 2000 ppm. Typical melting and atomizing practice requires strict control to produce a quality product.

Compositions and hardnesses of several typical alloys are given in Table 2. Detailed information on cobalt hardfacing alloys can be found in the article "Welding and Hardfacing Powders" in this Volume.

Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum

Howard D. Glicksman, DuPont Company

Introduction

PRECIOUS METALS are used extensively in such advanced material applications as electronic components, fuel cell electrodes, and high-performance catalysts. Fine precious metal powders are used in the electronics industry for the manufacture of fired conductors, multilayer ceramic capacitors, and conductive adhesives using thick-film technology. Multilayer ceramic capacitors are small electronic chips built up of alternating thin layers of nonconducting ceramic material sandwiched between an equal number of thin layers of the conducting electrode layer. The precious metal powders most commonly used are silver, gold, palladium, platinum, and combinations such as silver-palladium and gold-platinum. Excellent conductivity, corrosion resistance, good solderability, and stability in air during firing of the metal ceramic films make precious metals the preferred electronic material for high-performance applications (Ref 1). The cost of using these more expensive materials is more than outweighed by their ease of firing, subsequent stability in air, and ease of attachment by soldering and welding (Ref 2).

Precious metal pastes are used in a variety of sensors including systems for measuring oxygen, humidity, dew point, wind speed, flow rate, pressure, and temperature. These sensors make use of the catalytic characteristics of the metals as well as their moisture resistance, heat resistance, and conductivity. Gold, platinum, rhodium, and ruthenium are the principal precious metals used (Ref 3).

The conductor pastes used in thick-film applications generally contain four components consisting of the metal powder, a glass powder included as a bonding agent for joining the metal to the substrate, an organic vehicle containing an organic resin that imparts the needed rheology to the paste for screen printing, and a solvent to control the viscosity and solids content. The particle sizes for the metal powders range from 5 μm down to less than 0.1 μm . Uniform size distributions and spherical morphology are prerequisites for a good conductor paste. Precious metal particles with two-dimensional flake morphology are also used and are preferred for the manufacture of conductive adhesives and for polymer thick-film applications where the precious metal powders are not sintered.

The majority of these fine precious metal powders are prepared by chemical precipitation from an appropriate aqueous salt solution (Ref 1). Homogeneous nucleation is the prerequisite for fine, smooth, and dispersed metal particles made by chemical precipitation. Any heterogeneous nucleation needs to be suppressed. In addition to controlling the nucleation mechanism, the prevention of aggregation or coagulation of the fine particles precipitating out of the solution is equally important. Van der Waals attraction forces are responsible for coagulation, while electrostatic repulsion forces arising from the electric double layers surrounding the particles act against coagulation. Without controlling the attraction forces, the particles will become flocculated, making it very difficult to control the size of the powders. Generally, changing the surface potential of the particles via adsorption of surfactants is the method used to prevent aggregation. By precipitating the metal powders directly from an organic phase, which can provide uniform and enhanced steric stabilization with no stabilization by electrostatic repulsion, finer and smoother particles are obtained (Ref 1, 2).

Chemical precipitation begins with the preparation of the metal-soluble salt solution by dissolving the metal in an inorganic acid, such as nitric acid or aqua-regia (hydrochloric acid and nitric acid). When aqua-regia is used, the nitrosyl compound must be removed by continuous boiling with the addition of more hydrochloric acid. In the manufacture of binary or ternary metal powders, such as palladium-silver or platinum-palladium-silver, the metal salts are dissolved in a common solvent (can be water) prior to precipitation.

Platinum-group metal salts in aqueous solution when treated with reducing agents such as formaldehyde, sodium formate, hydrazine, and so forth, precipitate a finely divided metal powder. Most often the reduction is carried out in alkaline solution, although acidic reductions have been used (Ref 4).

By applying wet, continuous comminution to precious metal powders, in the presence of a proper lubricant and solvent, platelike precious metal flake particles can be successfully produced. Various types of milling equipment can be used including ball mills, vibratory mills, and attritor mills. The size, shape, and other physical characteristics of the milled particles are primarily controlled by the morphology of the starting metal powder, the lubricant chosen, the solvent, the milling media, and the milling conditions such as temperature, revolutions per minute, the ratio of powder to solvent, and overall time.

Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum

Howard D. Glicksman, DuPont Company

Production of Silver Powders

Silver powders are used in a variety of electrical, electronic, and industrial applications. In powder metallurgy, silver powders are used in the manufacture of electrodes for primary batteries and storage cells, and as mixtures with other metals that are used in the preparation of electrical contacts and other P/M parts containing silver. These mixtures include silver-tungsten, silver-iron, silver-tungsten carbide, silver-molybdenum, silver-cadmium oxide, silver-graphite, and silver nickel (Ref 5). These electrical applications generally require a dense, coarse silver powder of high purity with good compressibility. Average particle sizes vary from approximately 10 to 100 μm .

In the electronics industry, silver powders are used in conductive inks, pastes, and adhesives. Conductive silver inks were probably the first thick-film inks to be developed and are used in the manufacture of capacitors, potentiometers, printed circuits, and other electronic parts. Silver pastes for glass substrates are heated up to 650 °C and are used in such applications as fluorescent character display tubes, plasma displays, heaters for kettles, hot trays, automobile antennas, and heated automobile windows (defoggers). Lower-temperature silver pastes containing cured polymers are used as conductive films for electromagnetic shields, undercoat for copper plating, membrane switches, flexible substrates, and amorphous solar cells. Silver pastes are also used as conductive adhesives for connecting leads to terminals and components on substrates or components to components. Examples include die-attach materials, lead wire outlets of quartz oscillators, silicon die bonding, and bonding of sliding carbon brushes to the lading springs (Ref 2).

The value of using silver is that it is the least expensive precious metal that is compatible with the normal thick-film process and can be made to have good bond strength with very high conductivity. Although its leach resistance to solder can be poor, slight modifications to the solder can help overcome this problem. Silver compositions are also easily compatible with resistor and dielectric systems. The major disadvantage of silver is its strong tendency to migrate over the surface of insulators and resistors when subjected to electrical fields under conditions of higher humidity. The rate of migration is considerably reduced in silver alloys, but migration is always a concern with silver-bearing conductors (Ref 6).

Generally, silver powders used in electronic processes are chemically precipitated, exhibit high purity, and are small in size. Average particle sizes range from 10 μm to below 1 μm . Silver powders that are mechanically milled into flat powders or silver flakes are also used to provide more surface coverage of the substrate. These flakes are well suited for conductive coatings and shielding materials and are mixed with silver powders in conductive ink systems.

Other industrial applications of silver powders include water purification, catalyst manufacture, dental amalgams, and preparation of silver alloys. In addition, silver powders are used as a protective coating against hostile industrial environments and as a source of very-high-purity silver (99.99+% pure).

Most of the methods currently used to manufacture metal powders can be applied to the production of silver powders. Chemical, physical (atomization and mechanical), thermal decomposition, and electrochemical processes are used industrially to make silver powders. These powders can be characterized by physical properties including surface area, tap density, particle size, particle size distribution, and shape.

Chemical Processes. Most silver salts are easily reduced from solution, with limitations imposed only by their solubilities. The most common salts are silver nitrate and silver oxide. Organic reducing agents such as alcohol, sugar, or aldehydes are used to manufacture silver powder from silver oxide. For example, dextrose can be used to produce a very fine silver powder:

Organically precipitated silver powders have small particle sizes with average sizes ranging from 5 to less than 0.1 μm . Unfortunately, these silver powders tend to agglomerate into aggregates of 10 μm or larger. To avoid agglomeration, the

powder can be precipitated in the presence of a surfactant or deagglomerated after the precipitation using mechanical processes such as high shear mixing, ball milling, or jet milling. It was found that the addition of a surfactant such as gelatin can control the particle size of silver powder produced from the reduction of silver oxide with formaldehyde. For this reaction, it is important to control the amount of sodium hydroxide and gelatin, the formation of the silver oxide, and the temperature (Ref 7):

Inorganic reducing agents such as hydrazine, potassium sulfite, and sodium formate are used to reduce silver nitrate to silver powder. Two examples of the reduction process are:

These powders are coarse in size, resembling those made by electrochemical methods. Average particle sizes vary from less than 1 to 20 μm . These powders exhibit good flow and good sintering characteristics. Chemically precipitated silver powders can be made in a range of sizes and shapes. Examples are shown in Fig. 1, 2, and 3.

Fig. 1 Irregular-shaped silver powder

Fig. 2 Small-sized silver powder

Fig. 3 Spherical-shaped silver powder

Electrochemical Processes. Several electrochemical processes are used to manufacture silver powders. Galvanic reduction precipitates silver powder from a solution by a more anodic metal such as zinc, copper, or iron (Fig. 4). This process produces an irregularly shaped powder with a free bulk density ranging from 1.5 to 4.0 g/cm³. Particle sizes of 100 μm or more are produced by galvanic reduction. Some galvanically reduced powders exhibit good flow characteristics.

Fig. 4 Galvanic reduction

In electrolytic reduction, an electrical current passes through an electrolyte at room temperature to produce a crystalline silver. Current densities vary from 215 to 2150 A/m² (20 to 200 A/ft²), depending on the desired particle size. Silver anodes, usually as cast silver bars or granulated silver, are dissolved. Crystallized silver is then grown on a cathode in an experimental setup such as that shown in Fig. 5. This crystalline silver powder is dendritic and can be very large, with particle sizes ranging from 1 μm to as large as several millimeters, depending on processing conditions and current densities (Ref 8).

Fig. 5 Electrochemical reduction

Atomization and Aerosol Processes. Atomization of a molten stream of silver with gas or liquid is used to produce silver powder. The atomized powder generally approaches a spheroidal shape, with a very smooth surface, minimal porosity, and a very high powder density. Average particle sizes generally are 10 to 50 μm , and physical classification is usually required to provide a narrow size distribution. The average particle size can be shifted by adjustment of the gas velocity, design of the atomization die, and by control of the metal feed (Ref 5).

Aerosol routes can be used to produce silver powders. Solid, spherical, dense silver powders can be produced by spray pyrolysis (aerosol decomposition). An aerosol of a silver salt solution such as silver nitrate is heated to temperatures as low as 600 °C in nitrogen to decompose the silver salt and produce a fully dense silver powder. Spherical silver powders of different sizes and density can be made by controlling reaction temperature, carrier gas, solution concentration, residence time, and droplet size. Particle size of the silver powders range from 5 to smaller than 0.5 μm (Ref 9).

Another spray pyrolysis technique for making silver powders involves the spraying of a silver nitrate solution into a flame formed by a coaxial burner. Control of the flame temperature and the spray conditions allow for the control of particle size and shape. By adjusting the flame temperature, particles can be made nonspherical (temperatures below the melting point), spherical (temperatures above the melting point), and ultrafine particles by having the flame temperature sufficiently hot enough to evaporate the silver (Ref 10).

Mechanical Milling Processes. Mechanical comminution can be used to alter most types of silver powders with processes such as ball milling, vibratory milling, or attrition milling. These methods are time consuming and care needs to be taken to keep from introducing significant levels of impurities from the equipment and media. Many types of milling media can be used including glass balls, zirconia balls, and metal balls. Sizes of media range from 10 to less than 1 mm depending on the size of the starting silver powder and the size of the resulting silver flake desired. Initially, larger silver particles and silver agglomerates are broken down during the milling process. Continued milling produces flat, two-dimensional silver flake as shown in Fig. 6. Usually an organic surfactant is introduced during the milling process to prevent the cold welding of the particles to each other during the grinding process and to control the size and shape of the silver flake. Typical surfactants include saturated and unsaturated fatty acids and long-chain aliphatic molecules. By altering the surfactant, solvent, milling media, and milling conditions, specific silver flakes can be designed for particular applications (Ref 11).

Fig. 6 Silver flake

Thermal Reduction. Heat is used to reduce silver salts to produce silver powders. Silver oxide and silver carbonate can be reduced to silver powder by thermal reduction in an inert atmosphere at temperatures greater than 250 °C (480 °F) as follows:

These powders tend to be spongy, agglomerated, and very porous and therefore require subsequent mechanical treatment to provide usable silver powder.

Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum

Howard D. Glicksman, DuPont Company

Production of Gold Powders

The reliability of gold conductors makes them highly desirable for a variety of applications in electronics and communication systems. In hybrid microcircuitry it is the bonding behavior of gold as well as its electrical conductivity that makes it desirable. The reliability of gold is largely due to its superior resistance to oxidation and tarnish. Using gold initially may cost more, but much more would be sacrificed in terms of lost operating time and repair expenses if the electrical properties of the nongold substitute were to deteriorate due to the formation of oxide or sulfide films (Ref 6, 12).

Pure gold conductors have high conductivity, excellent wire bondability, excellent migration resistance, and are generally compatible with other components of thick-film materials. This makes gold particularly suitable for resistor terminations, wire- and die-attach pads, and highly reliable electrical interconnections (Ref 13). Applications for these devices include medical equipment, computers, satellite telecommunications, automotive control devices, and defense-related electronic components.

Pure gold conductors are not readily solderable using conventional solders because of poor solder leach resistance. The gold conductors can be made to be solderable through the addition of platinum. This imparts solderability at the expense of conductivity. Where high reliability and solderability is required and cost is not an issue, platinum-gold conductors are the industry standard (Ref 13, 14).

Many processes for making gold powder use an aqueous solution of chloroauric acid (HAuCl_4) as the starting salt solution. This gold chloride solution is made by dissolving gold grain or shot in aqua-regia (a 3-to-1 mixture of hydrochloric acid and nitric acid) followed by heating to decompose and remove the nitric acid.

A variety of reducing agents can be used to reduce gold to gold powder including other metal powders (zinc, magnesium, lead, aluminum, and iron), sulfur compounds (sulfur dioxide, sodium sulfite, potassium sulfite, and ferrous sulfate), hydrazines (hydrazine hydrate, hydrazine hydrochloride, and hydrazine sulfate), aldehydes (formaldehyde), oxalates (oxalic acid and potassium oxalate), hydrogen peroxide, hydroquinone, hydroxylamine, and hypophosphorous acid (Ref 15, 16).

The morphology of the gold particles is determined by the conditions of the precipitation process. Using reducing agents without the addition of particle morphology modifiers produces gold particles with nodular or irregular-shaped particles. Heating the solution increases the rate of reduction. The presence of free hydrochloric acid can retard or even prevent the reduction. Solutions that are basic can increase the rate of reduction (Ref 17). Sodium hydroxide, sodium carbonate (or bicarbonate), and amines (including ammonia) can be used to make the solutions basic and regulate the pH during the reaction.

Reproducibility and morphology are the keys to the applications for gold powder and are the driving forces for choosing one process over another. Gold powder can be precipitated in a wide range of particle size distributions and shapes. Different reducing systems produce different types of gold powders. Modifiers can be added to control the nucleation stage to closely control particle size, and colloidal materials can be added to inhibit particle-to-particle aggregation (Ref 18).

The shape characteristics of gold powder are almost entirely spherical where the reductants are sulfur dioxide, sulfites, and related compounds. Potassium sulfite or sodium sulfite can be directly added to aqueous gold chloride solution to produce spherical gold particles with controlled size and density (Ref 19):

This reaction is very dependent on pH, the ratio of gold chloride to sulfite, the mixing, and the temperature. If high temperatures are used, a mixture of spheres and flat plates can be made (Ref 16).

Gold powder containing a mixture of gold flakes and gold spheres can be made by reducing an aqueous gold chloride solution with a mixture of hydroquinone and oxalic acid in the presence of a protective colloid such as gum arabic, methylcellulose, sodium alginate, gelatin, and so forth (Ref 20). Fatty acids, fatty acid alcohols, and fatty acid amines can also be used as coatings for the gold particles to control the particle size and act as lubricating agents when using the gold powders (Ref 21).

An example of spherical gold powder is shown in Fig. 7, and a gold powder containing a mixture of spheres and flakes is shown in Fig. 8.

Fig. 7 Spherical gold powder

Fig. 8 Gold powder containing flakes and spheres

Gold powder can also be made mechanically. Sheets of gold are reduced in thickness by rolling and beating to produce a foil between 0.001 and 0.002 cm thick that is then beaten to produce a gold 0.2 to 0.5 μm thick. These leaves are broken down further during a dispersion process to enable them to be used as fine gold powder. Larger gold powders and gold flake can be made through standard ball milling of gold powder (Ref 18).

Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum

Howard D. Glicksman, DuPont Company

Palladium Powders

Palladium is used in the electrical and electronics industries in electrical contacts, multilayer ceramic capacitors, thick-film paste conductors, resistors, thermocouples, and heating pads. The corrosion resistance, high melting point, contact resistance, and reasonable electrical conductivity of palladium account for its use as an electrical contact material where long life and reliability are essential. Palladium can be preferred for low-current, long-life relays operating at low contact forces (Ref 22, 23).

Palladium powders, mixtures of silver and palladium powders, and palladium-silver alloy powders are used extensively as the electrode material in multilayer ceramic capacitors. Palladium pastes are used in multilayer ceramic capacitors made at high temperatures, whereas silver-palladium is used in capacitors prepared at lower fired temperatures. The properties of the powders intended for the internal electrodes of multilayer ceramic capacitors are extremely important as compatibility is required between the metal powder and the organic medium of the thick-film paste and between the paste itself and the surrounding dielectric material (Ref 24).

Other thick-film conductor applications for palladium powders include chip resistors, resistor networks, and hybrid conductors for industrial, automotive, telecommunications, and even high-technology consumer applications (Ref 25). The presence of palladium serves to inhibit the solder leaching of silver from the conductor circuit line, and it reduces the migration of the silver into the dielectrics or resistors in hot or humid conditions, especially when high electric fields are present between closely adjacent conductor tracks held at different electric potentials (Ref 13).

As with other precious metal powders, soluble palladium salts such as chloropalladous acid, palladium nitrate, and palladium bromide are chosen as starting materials. Chloropalladous acid is the most frequently used. However, for the production of precious metal powders involving silver by coprecipitation, chloride salts should be avoided because they immediately precipitate the silver ions to form insoluble silver chloride. To prevent the precipitation of insoluble silver chloride, the nitrate salts of palladium and silver are used when making coprecipitated silver and palladium. Prior to reduction, the pH of the aqueous solution of the reactants may be adjusted by the addition of ammonium hydroxide, sodium, or potassium hydroxide, sodium or potassium carbonate, or similar compounds.

Although the basic reaction for making palladium powder remains the same:

subtle variations in the reaction parameters can have a large effect on the physical characteristics of the metal powder formed. Reducing agents that are effective for gold or platinum precipitations are applicable for the manufacture of palladium powder. Hydrazine, formaldehyde, hypophosphorous acid, hydroquinone, sodium borohydride, formic acid,

and sodium formate are used. Important variables in the reduction process for making palladium powder include the type of palladium salt used as the source of palladium, the type of complexing agent (if any), the pH, the choice of the reducing agent, the concentration of the reactants, the reaction temperature, the mode and degree of agitation of the solution, the solution viscosity, and the presence of additives or surfactants. Subtle changes to the precipitation parameters can produce different sizes ranging from <0.1 to greater than $5\text{ }\mu\text{m}$ and different morphologies including nodular, dendritic, irregular, and spherical-shaped palladium particles (Ref 24). Examples of palladium powders are shown in Fig. 9 and 10.

Fig. 9 Small-sized palladium powder

Fig. 10 Spherical palladium powder

Metal powders such as zinc and copper can be used to produce palladium powder from acidic solution. This process is known as "cementation" or "galvanic precipitation." The reaction is:

Generally, products prepared by this technique require special treatment to reduce the amount of impurities present. In addition, these palladium powders are large in size, irregular shaped, and tend to be agglomerated.

Spherical, dense palladium powder can be produced using spray pyrolysis. A precursor palladium salt solution (such as palladium nitrate) is atomized by an aerosol generator, the droplets are evaporated and reacted in a furnace, and the resulting spherical palladium powder is collected. The parameters controlling the particle properties include the choice of palladium salt, reactor temperature, solution concentration, aerosol droplet size, reaction atmosphere, and the residence time in the reactor. By controlling these parameters, spherical, dense palladium particles can be made with average sizes ranging from 0.1 to about $5\text{ }\mu\text{m}$ (Ref 26).

Production of Precious Metal Powders: Silver, Gold, Palladium, and Platinum

Howard D. Glicksman, DuPont Company

Platinum Powders

Platinum is the noblest of all of the metals. Despite its great expense, it is the best known of the precious metals and is widely used. Platinum has a very high density, does not corrode, and is very chemically resistant. With its low, but temperature-dependent resistance, platinum is used for temperature measurement, corrosion-resistant electrical contacts, electrodes, and sensors for gas detection such as oxygen and toxic gases (Ref 27). Oxygen sensors are used in automobiles to monitor the exhaust gases to ensure that the autocatalysts are working and that the fuel-to-air ratios are optimal. Platinum sensors can be used as flow-rate sensors because they have a quicker response than the conventional wire-type sensors (Ref 3). Platinum is also used for applications that need to endure severe conditions so that the added expense relative to palladium or silver is necessary to provide the reliability and durability (Ref 22).

Platinum powders are used in thick-film pastes as spherical or flake-shaped particles with size ranges from 0.1 to 20 μm . An example of platinum powder is shown in Fig. 11. These pastes are sprayed, brush-painted, or screen printed onto inert surfaces that are then fired to 500 to 1500 $^{\circ}\text{C}$ to form strongly bonded conductors that can be soldered (Ref 22). In addition, small amounts of platinum powders can be added to silver thick-film pastes to improve the bondability and leach resistance of the formed conductor film. Platinum powders are added to gold-powder thick-film compositions to impart excellent solder leach resistance. These platinum gold conductors are the standard for high-reliability, solderable conductor applications where cost is less of an issue (Ref 13).

Fig. 11 Platinum powder

An aqueous salt solution of chloroplatinic acid (H_2PtCl_6) is the most common starting material for the manufacture of platinum powder. It can be prepared by dissolving platinum sponge in aqua regia. After the nitric acid is driven off by continuous boiling with the addition of hydrochloric acid, the solution is then precipitated by a suitable reducing agent at the proper pH level. Reducing agents that are used include sodium formate, formic acid, sodium borohydride, sodium hydrosulfite, hypophosphorous acid, and hydrazines. The pH of the solution can be adjusted by the addition of reagents such as sodium, potassium, or ammonium hydroxides, or their carbonates. Sodium borohydride can be used in the preparation of platinum alloys including ruthenium-platinum, platinum-palladium, platinum-rhodium, and platinum-iridium (Ref 4).

Very small sized platinum particles are very active and commercially important as catalysts. One method of making platinum powder with a size of about $0.030 \mu\text{m}$ is the reduction of chloroplatinic acid with sodium borohydride. The reaction is as follows:

An organic protective agent such as poly(vinylpyrrolidone) is generally added to prevent coagulation of these small platinum particles (Ref 28).

Production of Refractory Metal Powders

Introduction

THE REFRACTORY METALS--tungsten, molybdenum, niobium, tantalum, and rhenium--are distinguished by several common characteristics, including high density, high melting point, and superior resistance to wear and acid corrosion. Tungsten, for example, has a density over twice that of iron and a melting point of 3410 °C (6170 °F), the highest of any element. These metals have body-centered cubic crystal structures (with the exception of rhenium, whose crystal form is hexagonal). All are subject, however, to severe oxidation above 500 °C (930 °F) and must be protected for service by coatings or nonoxidizing atmospheres.

The refractory metals are extracted from ore concentrates, processed into intermediate chemicals, and then reduced to metal, which can be in the form of powder. The pure or alloyed powders are pressed, sintered, and subsequently worked. This article discusses the raw materials, processing steps, powder properties, and finishing techniques (blending, handling, inspection and packaging) involved in the production of refractory metal and carbide powders. For information on applications of these materials, see the article "Refractory Metals" in this Volume.

Production of Refractory Metal Powders

Production of Tungsten and Tungsten Carbide Powders

B. Lux, Vienna University of Technology; B. Zeiler, Wolfram Bergbau- und Huetten-GmbH Nfg KG

Tungsten gained major industrial importance at the beginning of the 20th century due to its technical application as alloying element in high-speed steel and as filament wire in incandescent lamps (Ref 1, 2, 3). For both applications, pure tungsten was produced in powder form. From 1900 to 1912 only pure tungsten powders were used in high amounts for high-speed steels containing 16 to 24% tungsten (Ref 1). This application dominated the tungsten consumption at the time, but around 1915 ferrotungsten replaced the tungsten metal powder in this application.

Later (1910-1920), diamonds were needed in large numbers to produce drawing dies for tungsten lamp wire fabrication. Due to their high costs, there was a strong driving force to find cheaper alternatives. At this time, the very hard tungsten carbides (WC and W₂C), studied by Henri Moissan at the end of the 19th century during his attempts to make artificial diamond (Ref 3, 4), were considered as appropriate alternatives. However, all trials to compact tungsten carbide powders resulted in porous and brittle products unusable for the anticipated drawing dies application. In 1922, researchers of the OSRAM study group combined the brittle tungsten carbide with a ductile metal binder (iron, cobalt). After sintering the respective powder mixtures, a material of both high strength and toughness was obtained. Thus the "hardmetal" also named "cemented carbide" was created. OSRAM used the new material mainly for wire drawing. Since they apparently did not yet realize the great importance of their invention, patents were applied for in only Germany, Great Britain, and the United States, while in all other countries, priority deadlines were missed (Ref 3).

In 1925 KRUPP, a company experienced in steel technology and tool manufacturing, realized the enormous potential of the hardmetals and bought the patent rights. In 1927 they introduced hardmetals under the brand name WIDIA (an

abbreviation for WI-e DIA-mant, which in German means "similar to diamond") (Ref 3). Since then, cemented carbides have changed the tungsten consumption pattern completely; today, hardmetals (and thus tungsten carbide powders) account for more than half of the world's tungsten consumption (Ref 5, 6, 7, and 8).

Production of Refractory Metal Powders

Uses and Annual Consumption

A breakdown of tungsten usage in the three most important economic regions-- United States, Japan, and Europe-- is shown in Fig. 1 (Ref 5, 6, 7, and 8). Over the last 20 years, annual global consumption of tungsten has been in the range of 40,000 to 50,000 metric tons per year (Ref 9). As noted, over half of tungsten consumption is for tungsten carbide powder for hardmetal production. However, important products are also based on tungsten metal powders, such as:

- Heavy metal alloys (W/Fe/Cu/Ni/Co-alloys)
- Electrical contact materials (W/Cu, W/Ag)
- Ductile tungsten (including lamp filaments)

Tungsten, as an alloying element for steels and superalloys, is predominantly used as ferrotungsten, or as melting base alloys, which are prepared from either ore concentrates or tungsten-bearing scrap. Tungsten powders are hardly used for this application. A minor part of the tungsten consumption is used in the form of various chemical products, such as catalysts, pigments, solid lubricants, and heavy liquids (Ref 10).

Fig. 1 Breakdown of tungsten consumption for different economic regions. Source: Ref 5, 6, 7, and 8

Production of Refractory Metal Powders

Tungsten Metal Powder

Production

Industrially relevant tungsten-bearing minerals are Wolframite ($[\text{Mn}, \text{Fe}] \text{WO}_4$), Ferberite (FeWO_4), Hübnerite (MnWO_4) and Scheelite (CaWO_4). The tungsten concentration of workable ore starts at 0.1 to 0.3 wt% WO_3 . Concentrations of more than 2 wt% are rare. The average WO_3 content is usually about 0.5 wt% (Ref 11, 12, 13). Depending on the mineral type, different techniques are used to concentrate the ore up to typical WO_3 contents about 60 to 70%, such as gravity methods and flotation. An important alternative tungsten source to the natural mineral resources is tungsten-bearing scrap, which usually has a high tungsten content.

Process. Figure 2 schematically shows the process from the concentrate or scrap via the formation of the high-purity ammonium paratungstate (APT) intermediate to tungsten metal powder (Ref 11, 14, 15).

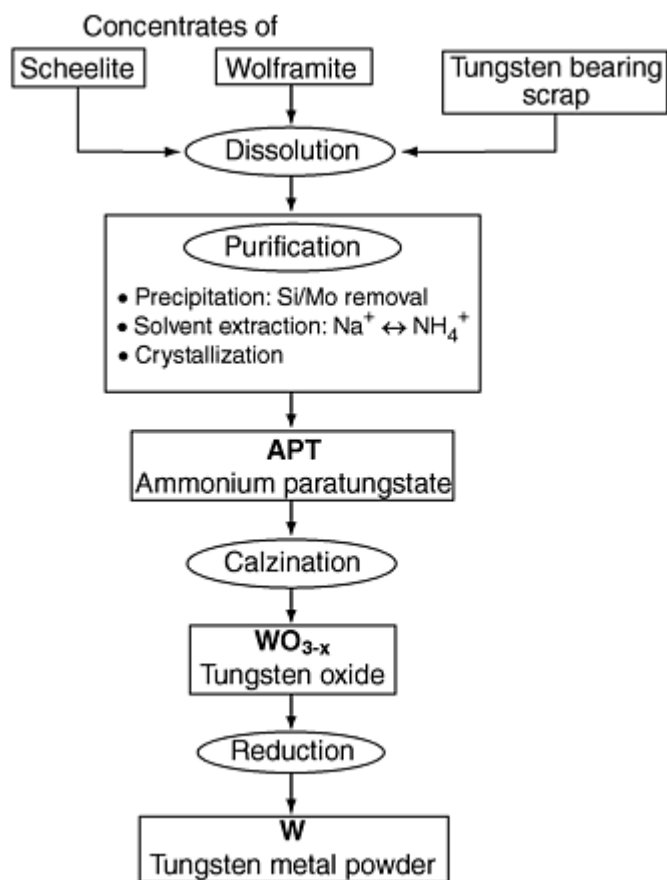

Fig. 2 Production of tungsten metal powder

Dissolution Step. The tungsten-bearing raw materials are treated with NaOH (Wolframite and oxidized scrap) or Na_2CO_3 (Scheelite) to form water-soluble sodium tungstate (Na_2WO_4).

Purification steps are as follows:

1. Silicon, phosphorus, fluorine, aluminum, and arsenic are removed by precipitation.
2. Sodium is exchanged by NH_4 and an ammonium tungstate solution ($(\text{NH}_4)_2\text{WO}_4$) is formed. This is commonly done by solvent extraction (SX), which is a liquid ion exchange (LIX) process, where tungsten is extracted by means of an aliphatic amine dissolved in isodecanol and kerosene. Reextraction into aqueous ammonia solution finalizes this step.
3. Ammonium Paratungstate (APT) is crystallized by evaporation of ammonia and water. APT is the intermediate product of highest purity for tungsten metal and tungsten carbide powder production. Today other intermediates, such as tungstic acid, have practically no industrial relevance and have almost disappeared completely.

Calzination Step (Ref 16). By heating the APT to 400 to 900 °C, mainly in rotary furnaces, ammonia and water are removed leading to tungsten oxide. If carried out in excess of air, the resulting oxide is yellow (WO_3 - tungsten yellow oxide). Under exclusion of air (oxygen), a slightly reduced blue colored oxide is formed (WO_{3-x} , tungsten blue oxide).

Reduction Step (Ref 2, 11). The tungsten oxide is reduced by hydrogen to tungsten metal powder. Two different furnace designs for the reduction process are industrially used today, the multitube push type (Fig. 3) and the rotary furnaces (Fig. 4).

Fig. 3 Multitube push type furnace. Courtesy of Wolfram Bergbau- und Huetten-GmbH Nfg KG, Austria

Fig. 4 Rotary furnace. Courtesy: Wolfram Bergbau- und Huetten-GmbH Nfg KG, Austria

Push Type Furnace. The tungsten oxide is filled in flat metal "boats," which are pushed through the furnace tubes. This results in a static powder layer throughout the whole reduction process. Layer height and push cycle can be varied. Through individual heating zones temperature profiles may be applied. Typical reduction temperatures range from 600 to 1100 °C. The flow of hydrogen is usually in the countercurrent direction. Removal of the water vapor formed during reduction occurs from the powder layer surface and is effected by the hydrogen flow rate. By variation of reduction parameters like temperature and powder layer height (oxide load of the boat), the particle size of the tungsten metal powder can be controlled in the range between 0.1 and 100 μm . The throughput for production of fine powders is lower than for manufacturing of coarser ones. The push type furnace is very flexible with respect to the production of different particle sizes and can quickly be adjusted to produce the desired powder properties.

Rotary Furnace. The tungsten oxide is directly introduced into the rotating furnace tube. As a consequence, there is no static but a dynamic powder layer. Depth of the layer is influenced by the feed rate, rotational speed, incline, and lifters inside the tube. The temperature range is comparable to that of push type furnaces, and the hydrogen flow direction is also in most cases countercurrent. Concerning changes between particle sizes of the tungsten metal powder to be produced, the rotary furnace is not as flexible as the push type furnace. A typical application is the continuous production of medium sized, 1 to 3 μm powders.

Reduction in General. Although the technical process of tungsten oxide reduction is carried out in one single process step, it proceeds through several intermediate oxide phases, as illustrated in Fig. 5 (Ref 17). The sequence in which oxides occur depends on the applied temperature and the local humidity within the static (push type furnace) or the dynamic (rotary furnace) powder bed. The intermediate oxides differ not only with respect to their color but also to their morphology (Ref 17, 18), which is shown in Fig. 6 (Ref 18). The reason for these morphological changes is the transport of tungsten via the gas phase chemical vapor transport (CVT) during the reduction sequence (Ref 19, 20). $\text{WO}_2(\text{OH})_2$ has been identified as the most volatile compound in the system, W/O/H, and is responsible for the CVT (Ref 19, 20, 21, and 22). Figure 7 shows the CVT reaction from WO_2 to tungsten metal (Ref 23). If the partial pressure ratio, $p_{\text{H}_2\text{O}}/p_{\text{H}_2}$, is low enough, the reduction from WO_2 to tungsten (at a certain temperature) starts. From a thermodynamic point of view, $\text{WO}_2(\text{OH})_2$ may form from both WO_2 and tungsten, but the equilibrium pressure is lower above tungsten, which causes the CVT of $\text{WO}_2(\text{OH})_2$ from WO_2 to tungsten, where this vapor deposits as tungsten metal, thus leading to growth of the tungsten crystal. The CVT mechanism enables the control of the W-metal powder particle size through the interplay between temperature and humidity (partial pressure ratio, $p_{\text{H}_2\text{O}}/p_{\text{H}_2}$ which is shown schematically in Fig. 8 for the push type furnace (Ref 11, 19, 20, and 24).

Properties

Tungsten has two outstanding properties, a very high density of 19.3 g/cm³ and the highest melting point of all metals at 3422 °C (Ref 25) (Table 1). It can not be put in shape by normal casting technologies. Consolidation of tungsten powders is based almost exclusively on powder metallurgical techniques. Thus, clear and extensive powder specifications are extremely important for any industrial consolidation in order to obtain the desired final properties of a consolidated tungsten product. Tungsten powder properties and their proper specification can be divided in physical and chemical aspects.

Table 1 Properties of tungsten

Property	Value
Crystal structure	Body centered cubic
Density at 20 °C, g/cm ³	19.3
Hardness at 0 °C, HV	450
Modulus of elasticity at 0 °C, kN/mm ²	407
Melting point, °C	3422
Coefficient of thermal expansion at 500 °C, mm/m	2.3
Specific electrical resistivity at 20 °C, μΩ · m	0.055
Thermal conductivity at 0 °C, W/m · K	129.5
Vapor pressure at 1700 °C, Pa	1 × 10 ⁻¹⁰

Source: Ref 11, 25

Physical Properties. The particle size of the tungsten powder is very important for its use. Today all sizes, from submicron up to one hundred microns, are produced on an industrial scale (Fig. 9); today's major tungsten metal powder consumption is within the range of 2 to 5 μm.

Fig. 9 Tungsten metal powder particle size range. Courtesy: Wolfram Bergbau- und Huetten-GmbH Nfg KG, Austria

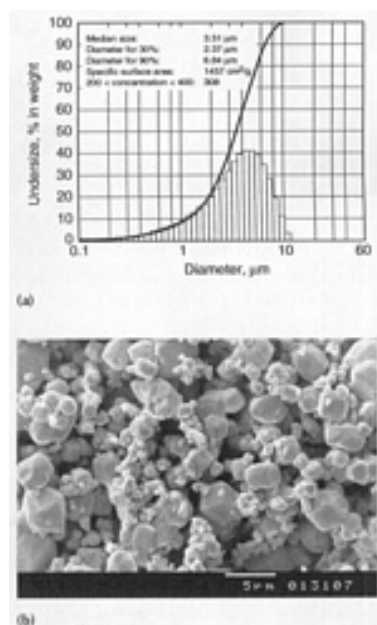

Particle sizes between 1 to 10 μm are measured by Fisher subsieve sizer (FSSS) (ASTM B 330, Ref 26) and correspond well to particle sizes observed directly by scanning electron microscopy (SEM). However below and above this range only SEM gives accurate values. SEM is also the best way to judge the overall grain morphologies and homogeneity.

Particle size distributions can be measured by sedimentation (Sedigraph) (ASTM B 761, Ref 26) or by laser scattering techniques (ASTM B 822 (Ref 26)). Appropriate regulations of reduction parameters permit to obtain both, narrow or broad, size distributions and to fulfill almost any specific requirement on tungsten powders needed for various applications.

Different powder density measurements, such as apparent or Scott density (ASTM B 212 and B 329, Ref 26), tap density (ASTM B 527, Ref 26) as well as green density are of great importance for predicting and controlling the behavior of a powder during the subsequent consolidation steps (i.e., pressing and sintering).

Chemical Properties. Generally, tungsten metal powders, in comparison with most other metal powders used for powder metallurgical products, have a relatively very high purity, as shown by a typical product analysis given in Fig. 10.

Trace elements, such as molybdenum, aluminum, silicon, phosphorus, arsenic, sodium, potassium, calcium, magnesium, and sulfur are already removed during APT production. The uptake of elements like nickel, chromium, iron, and cobalt, typical alloying elements of reduction boats or rotary furnace tubes, has to be prevented during metal powder production.

Tungsten Applications and Special Products

Ultrahigh Purity (UHP) Powders. Sputter targets for semiconductor manufacturing need ultrahigh purity (5N and 6N) tungsten metal powders. In particular, the incorporation of alpha emitters such as uranium and thorium, is very critical and has to be kept below 1 ppb. The mobile alkali ions (e.g., sodium and potassium) have to be kept below 0.1 ppm. Purification of preselected APT by multiple extraction and crystallization steps guarantees the required purity, where all production steps must be carried out and can be achieved only under clean room conditions (Ref 11, 27, 28).

Pure Tungsten Materials. For wire and sheet production, the tungsten powders are consolidated to rods by pressing and sintering the powder. In order to get a suitably high densification, high temperatures between 2500 and 3100 °C (Ref 2, 11, 29) are applied. Thereby, most impurities still present at this stage are largely removed by evaporation. The sintered tungsten bars thus obtained are swaged or rolled at elevated temperatures in order to produce either rods, which are further drawn to produce wires, or sheets. Such pure tungsten materials are widely used for high-temperature applications, for example in high-temperature furnace construction (Ref 2, 11).

Nonsag Tungsten. The "creeping" of tungsten wires in incandescent lamps during very high operation temperatures must be avoided. The filament should not sag. Accidentally and involuntarily discovered decades ago, this avoidance can be achieved by incorporating traces of potassium into the tungsten wires, thus successfully preventing the sagging of the tungsten filaments in light bulbs (Ref 2, 30).

Today's technology is to add a mixture of aluminum, silicon, and potassium into tungsten oxide prior to the reduction to tungsten metal. During this reduction, a certain part of the Al-, Si-, K-doping elements is enclosed into the tungsten metal powder particles. In the subsequent sintering of the pressed tungsten powder, aluminum and silicon evaporate, while potassium is too big to diffuse through the tungsten lattice. This procedure leads to an incorporation of potassium droplets as inclusions. During the wire drawing, the tiny potassium droplets are elongated and finally break into a multitude of tiny potassium bubbles in rows allocated parallel along the wire axis, which leads to an elongated interlocked grain structure. During recrystallization at elevated temperatures, the potassium bubbles stabilize very effectively by an effect analog to dispersion hardening, the movement of dislocations and thus the migration of the grain boundaries perpendicular to the wire axis. This particular structure is the reason for the nonsag properties of the tungsten wires in light bulbs (Ref 2, 11, 30, and 31).

Tungsten with Oxide Dispersions. Tungsten metal powder and thorium-containing compounds (such as ThO₂ or Th-nitrate) are mixed, pressed, sintered, and further processed to wire or sheets. They have two major applications (Ref 2, 11):

- Welding electrodes, whereby the high electron emission capability of Th is used for easier electric arc formation and its stabilization (Ref 32, 33)
- Improved physical properties (dispersion hardening) in tungsten sheets and wires for (e.g., vibration-resistant automotive lamps) (Ref 34)

Due to environmental health and safety regulations associated with the use of the radioactive thorium, alternatives have been developed. Lanthanum and cerium have proved to be potential candidates to substitute thorium in welding electrodes (Ref 32, 33). For certain lighting applications, however, suitable substitutes are still missing (Ref 32, 34).

Tungsten Composite Materials. Tungsten metal powder mixed with other powders, such as iron, nickel, copper, and cobalt (both individually or in combination) can be liquid phase sintered at about 1500 °C, forming so called "heavy metals." Applications are based on the high density (17-19 g/cm³) and ductility of this composite and include counter weights, high energy penetrators, and radiation shields (Ref 11).

A porous skeleton of pressed tungsten metal powder can be infiltrated with copper alloys, or silver, leading to composite materials. W/Cu (and W/Ag) composites are used as electrical contacts (Ref 35, 36) due to their high electrical conductivity and their stability against damage caused by electrical arc formation. Recent developments (Ref 37, 38) describe the production of W/Cu-composite powders, which can be directly pressed to shape and sintered, thus preventing the infiltration and machining steps, which is of particular importance with respect to the application as heat sink in the semiconductor industry.

Recycling

Actually almost all kind of tungsten products, if available in large enough amounts and economically feasible, are recycled today (Ref 11, 39). Even unsorted low grade scraps containing enough tungsten can be used as a raw material for the chemical APT production process or can be used for alloying in the steel industry (Ref 40). Nevertheless, any options or possibility to use sorted tungsten scrap directly is of course preferably applied for economic reasons (Ref 40). Typical examples include:

- Sorted production scrap of pure tungsten can simply be crushed in high energy mills (planetary mills) and can be directly reused for applications with lower quality demands.
- Turning chips of heavy metal, obtained during the shaping operations, can be converted into reusable powder by oxidation and subsequent reduction. Too large solid pieces can be machined into smaller parts to enable further recycling. The oxidation step leads to a total disintegration of the solid chips into oxide powder containing WO_3 and tungstates of iron, nickel, or cobalt. Subsequent hydrogen reduction leads to a metal powder, whereby all components (W/Fe/Co/Ni) of the original heavy metal are still present (Ref 40).
- Composite scrap mixtures, such as W/Cu, are difficult to oxidize and are therefore not suitable for chemical recycling as described above. Also the recycling via the steel industry cannot be recommended due to the detrimental effect of copper in steel. A possible alternative is salt melt digestion with $NaNO_2$, $NaNO_3$, and Na_2CO_3 mixtures. However, this method suffers from environmental problems due to the NO_x formation (Ref 40). An alternative would be the electrochemical recovery of tungsten (Ref 41).
- W/Th recycling has specific problems due to the radioactive radiation. Recycling in the steel industry has become almost impossible during the last years. Chemical recycling in the conventional process leads to insufficient separation of thorium and is therefore also not applicable. The only way to recycle this material is still under development and based on the electrolytic dissolution of tungsten in ammonia (Ref 42). The difficulty is to run the process in a way to prevent dissolution of any of the radioactive fission products.

Production of Refractory Metal Powders

Tungsten Carbide Powder

Conventional production of tungsten carbide powders accounts world wide for the major part of the tungsten carbide powder. This flexible process can produce tungsten carbide powders with particle sizes between 0.15 and 50 μm (Ref 43). This range offers products for almost all industrial applications and is briefly described below along with alternative methods.

Production

Conventional. The main production steps involve the use of tungsten metal powder, which is mixed with high-purity carbon black, filled into graphite boats, and pushed through a high-temperature furnace under hydrogen at temperatures above 1300 °C. In contrast to the reduction step for tungsten, temperatures are much higher, and single tube push type furnaces (Fig. 11) are used. The particle size of the tungsten metal powder, used for carburization, determines directly the particle size of the tungsten carbide powder (Fig. 12).

Fig. 11 Single-tube push type tungsten carbide powder production furnace. Courtesy: Wolfram Bergbau- und Huetten-GmbH Nfg KG, Austria

Fig. 12 Correlation between tungsten metal and tungsten carbide particle size for ultrafine and coarse powders. Courtesy: Wolfram Bergbau- und Huetten-GmbH Nfg KG, Austria

After cooling the tungsten carbide powder is deagglomerated by means of ball mills, jet mills, or crushers. The deagglomeration step just separates particles from sticking to each other and is not used to adjust the particle size (Ref 43). The final process steps are homogenization (in double cone blenders) and sieving.

Fine Grained Powder Production. Recently, there has been an increasing demand for tungsten carbide powders finer than $1\text{ }\mu\text{m}$. Together with the limitations of the conventional process concerning the lower efficiency of fine grained tungsten metal powder production (Ref 44) there has been a strong motivation to develop alternative production routes.

Tokyo Tungsten has developed the direct carburization of tungsten oxide (WO_3) as an alternative to the conventional process (Ref 45, 46, 47). This process is carried out today on an industrial scale. The main production steps are as follows:

- Production of pellets from a mixture of tungsten oxide with carbon black
- Subsequent reaction in rotary furnaces at temperatures up to $1600\text{ }^\circ\text{C}$ (Ref 47) to tungsten carbide powder in two steps: first the direct reduction of the WO_3 to tungsten by carbon under nitrogen, followed by carburization to WC under hydrogen. Particle sizes of 0.1 to $0.7\text{ }\mu\text{m}$ can be produced (Ref 47).

More recently another direct carburization process has been developed by Dow Chemical (Ref 48, 49, 50):

- A mixture of WO_3 and carbon black falls through a vertical reactor at temperatures around $2000\text{ }^\circ\text{C}$. Thereby the reaction time is typically a few seconds, leading to an intermediate mixture of W, W_2C , WC, and C.
- This product has to be subjected to a second, more conventional, carburization step.

The typical particle size range for these direct carburization processes is between 0.1 and $0.8\text{ }\mu\text{m}$, which is identical with the lowest limits of feasibility of the conventional process (Ref 43).

To produce powders finer than $0.1\text{ }\mu\text{m}$ (100 nm), so-called nanopowders, two processes were developed. The spray conversion process has been promoted by Nanodyne Inc. (Ref 51, 52). Aqueous solutions of tungsten and cobalt salts are "spray dried," subsequently reduced, and carburized with gas mixtures like H_2/CH_4 or CO_2/CO in a fluidized bed reactor. The product is a relatively large (about $75\text{ }\mu\text{m}$), hollow WC/Co composite powder particle, which consists of WC crystallites with a grain size of about 30 nm . This product must be milled in order to get a powder usable for being compacted (Ref 52).

The chemical vapor reaction (CVR) process, developed and patented by H.C. Starck (Ref 53) is based on the gas phase reaction of metal halides with different gas mixtures, to produce nanosized powders (5 to 50 nm). Production of tungsten carbide powder is possible in principle, although the process seems to be better suited for production of nitrides or carbides of other group IV and V refractory metals (e.g., TiN).

Coarse-Grained Powder Production. The conventional tungsten carbide powder production route is usually limited by the application of carburization temperatures around $2000\text{ }^\circ\text{C}$. With these temperatures, it is possible to carburize 50 to $100\text{ }\mu\text{m}$ tungsten metal particles, but the resulting product is polycrystalline (Ref 43).

The growth of tungsten carbide single crystals can be highly boosted by the use of a liquid phase, which is able to dissolve both tungsten and carbon. The Menstruum process (also called macro process) involves the formation of tungsten carbide within the melt of auxiliary metal, such as Fe (Ref 54, 55). Mixtures of tungsten ore concentrates, Fe_3O_4 , Al, CaC_2 , and/or C react exothermally (after ignition by using a starter) to form WC, Fe, CaO, and Al_2O_3 . Temperatures of about $2500\text{ }^\circ\text{C}$ are reached and complete reduction and carburization of about 22 tons of WC is achieved in 60 minutes. To get the tungsten carbide in powder form, the solidified auxiliary metal has to be dissolved, which is typically done with hot hydrochloric acid. Separation of the obtained tungsten carbide powder according to particle size is done by sieving operations. Menstruum tungsten carbide powders have a high extent of well faceted single crystal particles, contain approximately 0.2% Fe, and have typical particle sizes of 40 mesh (about $400\text{ }\mu\text{m}$) and below.

Properties and Applications

One of the most important properties of pure tungsten carbide is its high hardness (for properties, see Table 2), which is the basis for the application in hardmetals.

Table 2 Properties of WC

Property	Value
Crystal structure	Hexagonal close packed
Density, g/cm ³	15.7
Microhardness, dN/mm ²	2080
Modulus of elasticity, kN/mm ²	696
Melting point, °C	Decomposition, 2600
Linear coefficient of thermal expansion (20-400 °C), 10 ⁻⁶ /K	5.2
Electrical resistivity, μcm	22

Source: Ref 56

Hardmetals, also called "cemented carbides," achieve an optimized balance between the high hardness of the tungsten carbide and the high toughness of a ductile binder metal, such as cobalt, nickel, or iron, whereby optimal interfacial bonding is achieved (Ref 56, 57).

To produce hardmetals, WC and cobalt powders are mixed, pressed, and liquid phase sintered. The excellent wetting of WC by cobalt is one of the key properties. By variation of the tungsten carbide grain size (from below one micron to tens of microns) and the percentage of cobalt (between 3 and 30%), tailor-made properties of the hardmetals, (i.e., a great variety of different hardness to toughness combinations) can be obtained (Ref 56, 57, 58). A general rule thereby is the finer the carbide and the lower the cobalt content, the harder, but the less tough the composite is (Ref 59). Additions of other carbides such as TiC, TaC or carbo-nitrides (TiCN) are used industrially in particular for steel cutting grades (Ref 58). For more detailed information see the article "Cermets and Cemented Carbides" in this Volume. Tungsten carbide powder properties can be divided in physical and chemical aspects.

Physical Properties. There are a number of technologically measurable and characteristic values, giving information about the particle size and size distribution, quite similar to those described in the section "Properties" for tungsten metal powder. However, until now, none of these testing methods considered the fact that the tungsten carbide powder particles can be single or polycrystalline. Figure 13 shows that tungsten carbide particles with equal particle size may quite well differ concerning the size of the single crystal domains within the individual particles. Depending on the powder manufacturing process, the same particle can either be single or polycrystalline. This fact has indeed a strong impact on the behavior of the powder during the manufacturing of the hardmetal.

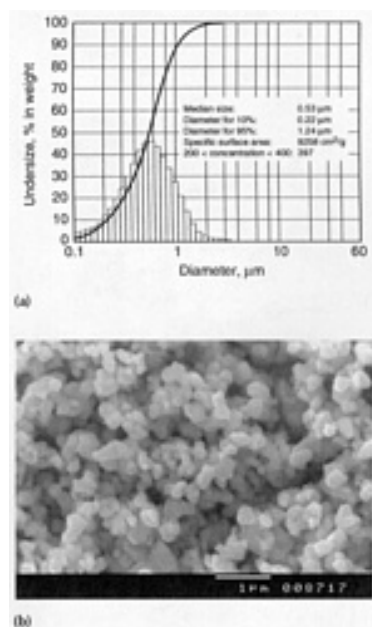

Fig. 13 Effect of crystallite size of tungsten carbide particles on their behavior during hardmetal manufacturing

Polycrystalline particles may separate during sintering in their individual subgrains. Thus the higher the number of subgrains per WC particle, the finer the microstructure of a hardmetal can be. This is very important for all powders with particle sizes larger than one micron. Below one micron and especially in the range of ultrafine tungsten carbide powders, there is the problem that even the measurement of the particle size becomes more difficult. It could be shown by scanning electron microscopy that powders with an FSSS particle size around $0.6 \mu\text{m}$ in reality were already as fine as $0.3 \mu\text{m}$ (Ref 43). Also the determination of the particle size through measurement of the BET surface area can be misleading for characterization of ultrafine tungsten carbide powders because of its sensibility for surface roughness. A coarse particle with high surface roughness may give a high surface area measurement, leading to the wrong conclusion, that it is much finer (Ref 43). In these cases, all the properties that can be measured in the powder can be taken to check the lot to lot reliability of one production process, but not to estimate the properties of the sintered hardmetal. These have to be evaluated by a test sintering. Other physical properties, such as Scott, tap, and green density are important to control or predict the shrinkage during sintering, which is essential because most of the hardmetal parts are sintered to size (near net shape).

Chemical Properties. The most important chemical aspect of tungsten carbide powder is its carbon content. Stoichiometric pure WC has a total carbon content (C_t) of 6.135 wt%. From a thermodynamic point of view, WC has a very narrow stability range (Rudy, 1969 in Ref 2, p 386). Thus, already small carbon deficiency leads to W_2C subcarbide formation and excess of carbon to the formation of free carbon (C_f). In industrially produced WC powders, there is always a small portion of free carbon present (about 0.03% at a stoichiometric C_t level). Even if the total carbon is below the stoichiometric level, the coexistence of traces of W_2C and C_f can occur. The carbon balance is quite important for hardmetal manufacturing, because a lack of carbon leads to the formation of the brittle eta-phases (e.g., $\text{Co}_3\text{W}_3\text{C}$) and any excess in carbon leads to graphite precipitation; both cases result in a detrimental effect on the mechanical properties of the final product (Ref 56, 58).

Because of their grain growth inhibiting effect during hardmetal sintering, elements such as vanadium, chromium, tantalum, and niobium are added intentionally to very fine WC, mainly below $1 \mu\text{m}$ (Ref 60), in amounts around 0.1 to 1.5 wt%. Such additions can be done as carbide to the tungsten carbide powder, or as oxide or carbide prior to the carburization step. Trace elements like nickel, iron, and cobalt can be tolerated in certain amounts (100 ppm and more).

However, there are other impurities that should be kept in the low ppm range due to their detrimental effect on hardmetal properties. Typical representatives are calcium, sulfur, silicon, and phosphorus (Ref 61, 62, 63). Figure 14 shows a typical example of an ultrafine tungsten carbide powder as commonly characterized.

Other Applications

Hardfacing. Carbide/metal mixtures very similar to hardmetal formulations are applied onto machine parts to improve their wear resistance. This can be done by flame or plasma spraying of powders or by welding electrodes. For this application, not only tungsten carbide powder as described above is used, but also so-called cast carbide, which is basically a crushed W_2C/WC mixture (Ref 56).

Electrical Contacts. A rather small quantity is used for the production of WC/Ag contact materials.

Diamond Tools. In diamond tool manufacturing, tungsten carbide powder (together with certain metal powders) are sometimes used to adjust the properties of soldering alloys in which the diamonds are embedded (Ref 56).

Catalysts. Some indications in the literature describe the use of very fine tungsten carbide with high surface area as catalyst in electrochemical reactions (Ref 64).

Recycling

Due to the fact that the majority of tungsten carbide powders are used for hardmetal production, this section focuses on recycling these products (Ref 65). Tungsten carbide containing hardmetal scrap can be divided into two groups:

- Soft scrap, which is powder scrap, such as hardmetal grinding sludge, filter dusts, floor sweepings, and broken green parts
- Hard scrap, which represents sintered parts, consisting of either production scrap or used parts

Another criteria for classification is the contamination of the scrap with impurities. While powder scrap frequently contains impurity levels that cannot be accepted for direct reuse, hard scrap, even if heavily contaminated, can be sorted, thus making a direct reuse easier.

Processes for hardmetal recycling (Fig. 15) can be divided into different categories (Ref 39, 65):

- Direct conversion into graded powder ready for pressing and resintering can be done with sorted hard scrap only. The most important process is the so-called "Zn process," shown schematically in Fig. 16 (Ref 39, 66, 67, 68, and 69). Also used on an industrial scale, but not as flexible from an economic point of view, is the coldstream process, shown in Fig. 17 (Ref 70). For more brittle hardmetals with low binder contents, mechanical crushing is also an alternative (Ref 65).
- Leaving the carbides as is, but removing the binder chemically is another way of hardmetal recycling (Ref 65). The composition of the hardmetal scrap used for the leaching process determines the quality of the resulting carbide residue.
- All contaminated scraps--either soft or hard--can be treated in the chemical conversion process (Fig. 18) to gain back virgin powders of the hardmetal constituents (Ref 65).

Due to the inherent value of the hardmetal constituents and due to the increasingly more severe legislation concerning waste disposal and preservation of natural resources, recycling has today a considerable importance, which will increase in the future (Ref 39, 71).

Production of Beryllium Powders

James M. Marder, Brush Wellman

Introduction

BERYLLIUM has a high elastic modulus (303.4 GPa, or 44×10^6 psi) and a low density (1.85 g/cm³, or 0.067 lb/in.³). It is used extensively in aerospace structures, weight- and inertia-critical structures, precision optics, and nuclear applications. Powder metallurgy is the primary fabrication technology used in the manufacture of beryllium products. This article discusses the techniques used to produce beryllium powder and the resulting material properties.

The production of beryllium powder begins with a vacuum-melted ingot, followed by chipping and mechanical or pneumatic pulverization. The mechanical properties of the final consolidated product depend on grain size and oxygen content, as well as on the method of powder production because it affects the crystallographic texture of the billet. Additional information on the properties, consolidation, and applications of beryllium can be found in the article "Powder Metallurgy Beryllium" in this Volume.

Powder metallurgy is used primarily to produce beryllium mill products, because the casting process does not produce parts with adequate structural integrity and mechanical properties. In making a beryllium structural casting, the degree of superheat that produces sufficiently low molten metal viscosity required for filling a mold cavity of any complexity also results in a very large as-cast grain size. Excessive grain size decreases strength and ductility. High superheat conditions can cause an excessive metal-mold reaction; insufficient superheat can result in a lack of mold fill, excessive porosity, or cold shuts. In addition, the reactivity and viscosity of molten beryllium exaggerate problems encountered when casting conventional materials.

The ingot/wrought billet manufacturing sequence also poses serious manufacturing difficulties. Columnar grain growth, which results from low-temperature ingot pouring, causes exaggerated planes of weakness at the impingement of the sets of columnar grains. Subsequent mechanical breakdown operations, therefore, result in cracking along the weak planes. Ultrasonic vibration (Ref 1) and the use of inoculants (Ref 2) are ineffective grain-refinement techniques. Zero-gravity experiments aboard Spacelab using beryllia and alumina as inoculants have also been ineffective (Ref 3). Powder metallurgy, therefore, is the only viable technique for manufacturing strong, homogeneous billets.

Production of Beryllium Powders

James M. Marder, Brush Wellman

Physical Properties

Beryllium has a close-packed hexagonal crystal structure with $a = 0.2286$ nm and $c = 0.3584$ nm and a c/a ratio of 1 to 1.56. This value is low compared to other metals such as titanium (1 to 1.58). Partly as a result of this c/a ratio, slip occurs almost exclusively on basal planes, with a Burger's vector of $b = \frac{1}{3}\langle 11\bar{2}0 \rangle$. Slip also can occur--with much greater difficulty, however--on first-order prism planes ($b = \frac{1}{3}\langle 11\bar{2}0 \rangle$), and with even more difficulty on second-order pyramidal planes ($\{11\bar{2}2\}$ with $b = \frac{1}{3}\langle 11\bar{2}3 \rangle$) (Ref 4).

Basal slip is the predominant deformation mode, however. Basal cleavage is the predominant fracture mode. These crystal structure characteristics affect the shape of powder particles and subsequently affect billet properties.

Production of Beryllium Powders

James M. Marder, Brush Wellman

Processing Sequence

Manufacturing a consolidated, fully dense beryllium product involves ingot melting and casting, powder manufacture, and consolidation. The consolidated product usually is a right circular cylinder that is made by vacuum hot pressing. This vacuum hot pressed billet can be readily machined into parts for satellites, aircraft, optical systems, or guidance instruments. Beryllium is particularly well suited to these applications because of its superior strength, modulus, and density. The ductility afforded by P/M processing also facilitates forging, rolling, extruding, and other hot-working processes.

Raw Material. Extraction begins with the mining of bertrandite ore, $\text{Be}_4\text{Si}_2\text{O}_7(\text{OH})_2$, and/or beryl ore, $3\text{BeO}\cdot\text{Al}_2\text{O}_3\cdot 6\text{SiO}_2$, from domestic and international sources. This is converted to crude beryllium hydroxide product, purified, converted to anhydrous beryllium fluoride, and reduced with magnesium to produce "pebble" or primary beryllium. Residual reduction slag containing these beryllium pebbles is purified by vacuum melting. Vacuum melting uses a magnesium oxide crucible and a graphite mold to produce an ingot weighing 180 to 200 kg (400 to 450 lb). The ingot is "skinned" (machined) to remove the high-carbon material adjacent to the mold wall. Next, a multihead cutting tool is used to reduce the ingot to chips. Standard P/M techniques are used for powder production at this stage.

Production of Beryllium Powders

James M. Marder, Brush Wellman

Powder Manufacture

Chips produced by the multihead cutter are relatively coarse and must be ground or comminuted to fine particle sizes before consolidation into a homogeneous, fine-grained billet. Before discussing grinding and comminution, however, it is important to recognize the effects that the close-packed hexagonal structure and chemical reactivity have upon the powder-making processes and the physical and mechanical properties of the final product.

During the late 1960s and early 1970s, mechanical attritioning and ball milling were used almost exclusively to reduce machining chips to powder. Mechanical attritioning is a rotary grinding procedure similar to the grinding of corn in a grist mill. Chips enter an area between a stationary and rotating beryllium plate, where they are ground. The particles then exit the mill at its periphery.

This process results in the occurrence of basal plane cleavage. Therefore, the powder particles produced by attritioning tend to be flakes, with large, flat surfaces corresponding to $\{0002\}$ basal planes. A scanning electron photomicrograph of attritioned powder is shown in Fig. 1. Ball-milled powders have a similar shape. As a result of their flat particle shape and lack of a truly random crystallographic texture, consolidated billets exhibit anisotropy of both physical and mechanical properties. During vibratory die loading for consolidation, the flat faces of many particles align, forming extended volumes with a common crystallographic feature. The basal plane corresponds to the flat faces.

Fig. 1 Scanning electron micrograph of flakelike attritioned powder. 270×

During consolidation--usually uniaxial vacuum hot pressing--the imposed stress causes these extended areas to rotate so that the c -axis poles align parallel to the stress axis. In billets made with attritioned powder, c -axis poles exist with two to three times the frequency in the longitudinal as compared to the transverse direction. The net result is substantial anisotropy of mechanical and physical properties. For example, ductility is substantially reduced in the longitudinal direction.

Impact grinding is used to minimize anisotropic effects. Figure 2 schematically illustrates the impact grinding process. Chips and powder are introduced into a high-pressure gas stream and are impacted against a beryllium target. The high speed of this pulverization process, coupled with relatively low temperature due to adiabatic gas cooling, activates the secondary and tertiary (nonbasal) cleavage systems.

Fig. 2 Impact grinding system

Resultant particles are blocky, rather than flakelike (Fig. 3). Consequently, there is a substantially reduced correlation between crystallographic basal planes and flat powder particle faces, leading to reduced anisotropy and an improvement in longitudinal tensile elongation (Ref 5). These effects are readily seen in Table 1, which illustrates the relationship between the method of powder comminution, {0002} pole density, and ductility.

Table 1 Comparison of billets using impact ground and attritioned powder

Powder lot ^(a)	Ductility and crystallographic orientation effects			
	Test direction	Tensile elongation, %	Elongation T/L ratio	{0002} pole density T/L ratio
Attritioned powder				
Lot A	Transverse	4.4	2.93 to 1	2.62 to 1
	Longitudinal	1.5
Lot B	Transverse	5.0	3.3 to 1	2.5 to 1
	Longitudinal	1.6
Impact ground powder				
Lot A	Transverse	5.0	1.7 to 1	1.48 to 1
	Longitudinal	2.9
Lot B	Transverse	5.4	1.5 to 1	1.45 to 1

(a) Powder lots A and B are produced from separate melts.

Fig. 3 Scanning electron micrograph of blocky impact ground powder. 270×

The transverse-to-longitudinal (T/L) basal pole density ratio and ductility T/L ratio for attrition milled powder are about 3 to 1. For impact-ground powder, these values are approximately 1.6 to 1. The isotropy of the impact-ground powder billet is improved, as is the minimum elongation value in any direction. This demonstrated correlation between crystal texture and ductility is causing attritioning to be gradually replaced by impact grinding.

The relationship of powder particle size to oxide content and grain size also affects billet properties. Beryllium obeys a Hall-Petch relationship, as shown in Fig. 4. As the size of the powder particles decreases, the oxygen content of the powder increases due to the increase in specific surface area. The mean free path between oxide particles also is reduced. Because oxides are a primary grain-boundary pinning agent, fine particle size enhances higher oxide content, finer grain size, and higher strength. The strength imparted by fine grain size and the potential embrittling effect of excessively high oxide content must be balanced against each other. Characteristics of powder used to produce commercial beryllium billets are given in Table 2.

Table 2 Characteristics of powder used for commercial beryllium billets

	Grade			
	SP-65B	SP-200F	IP-70	IP-220
Composition, %				
Beryllium assay, min	99.0	98.5	99.0	98.0
Beryllium oxide, max	1.0	1.5	0.7	2.2
Aluminum, ppm max	600	1000	700	1000
Carbon	1000	1500	700	1500
Iron	800	1300	1000	1500

(a) Each; determined by normal spectrographic methods

Fig. 4 Hall-Petch diagram of strength versus grain size of vacuum hot pressed beryllium with intermediate purity. Dashed line is yield strength values from Ref 6.

Gas Atomization. Inert gas atomization has been used to produce beryllium powder in semi-production quantities (Ref 8). The major advantage of this process over conventional impact ground powder is the increased isotropy of the consolidated product. This can be important in optical systems, in which isotropy is a primary factor in component performance, particularly in cryogenic systems wherein thermal contractions can cause distortion in anisotropic components. Economic benefits may also be realized if this technique is brought to production scale. As yet, the use of inert gas atomization has been confined to the advanced development stage, and no specification has been written for this material. The chemistry of a typical heat of inert gas atomized beryllium powder compares as follows with S-200F:

Impurity	Spherical powder, wt%	S-200 F, wt%
Beryllium oxide	0.32	1.2
Carbon	0.07	0.15
Iron	0.09	0.10
Aluminum	0.03	0.10
Silicon	0.02	0.06
Magnesium	0.01	0.06

Consolidation

Vacuum hot pressing is the traditional method by which beryllium components have been fabricated. Other methods, such as cold pressing and sintering and vacuum sintering, have also been used successfully to consolidate beryllium powder.

Vacuum hot pressing (VHP) typically is carried out at 1000 to 1200 °C (1830 to 3630 °F) and at a compacting pressure of approximately 8.3 MPa (1200 psi) or less. This process yields a product that is essentially 100% dense. Billets up to 183 cm (72 in.) in diameter have been manufactured by this technique. Properties of commercial vacuum hot pressed block are given in Table 3.

Table 3 Properties of beryllium hot pressed block

Property	Grade			
	S-200F	S-65B	I-70A	I-220B
Chemical composition, %				
Beryllium assay (min)	98.5	98.5	99.0	98.0

Elongation (min) in 25 mm (1 in.), %	2	3	2	2

Note: Pressing (billet) sizes can range from 18 to 183 cm (7 to 27 in.) in diameter and 15 to 168 cm (6 to 66 in.) in length, depending on grade and composition. (a) Special grades available with 9.000 permissible exposure limit (min) or 1.878 g/cm³ (min)

Hot isostatic pressing (HIP) is the consolidation method used for an increasing proportion of beryllium products and now approaches vacuum hot pressing in terms of the volume of material processed.

In the HIP process, the powder is loaded into a mild steel canister, degassed to remove air and water vapor, and the canister is sealed. Hot isostatic pressing takes place at a pressure of 103 MPa (15 ksi) with temperature in the range of 850 to 1000 °C (1560 to 1830 °F), depending upon the desired properties. A processed density in excess of 99.75% of theoretical is achieved in production. As a result of the greater latitude in consolidation temperature allowed by the use of HIP process, mechanical property improvements over conventionally vacuum hot pressed materials can be achieved. The specification mechanical properties of three grades of HIPed beryllium are compared to their vacuum hot pressed counterparts in Table 4.

Table 4 Comparison of beryllium specification mechanical properties for VHP and HIP

Property	Grade					
	S-200F		I-70		I-220	
	HIP	VHP	HIP	VHP	HIP	VHP
0.2% yield strength, MPa (ksi)	296 (43)	241 (35)	207 (30)	172 (25)	345 (50)	276 (40)

Elongation, %	3	2	2	2	2	2

A cold pressing/sintering/coining technique has been used successfully for specific applications, such as the production of aircraft brakes, heatsinks, rotors, and stators. The relationship of green density to pressure depends strongly on the specific powder used; a typical curve is shown in Fig. 5. After cold pressing to obtain a high green density, sintering is carried out in vacuum. An argon sintering atmosphere severely restricts final density, as shown in Fig. 6.

Sampling and Classification of Powders

Terence Allen

Introduction

WHENEVER POWDER is analyzed, whether for physical or chemical assay, the quality of the measurement depends upon how representative the sample is of the bulk from which it is drawn. The measurement may be made on a few milligrams taken from a bulk of many tons, so the chances of measuring a nonrepresentative sample are considerable. Therefore, sampling regimes and/or methods are needed to obtain representative samples for analysis.

In addition, classification methods are used to exclude certain powder sizes from a powder distribution, or to obtain particular powder distributions. Sieving methods, for example, are used to obtain particular powder distributions, or to obtain narrow size ranges of a powder.

This article briefly summarizes sampling, classification, and sieving methods for powders. The properties of metal powders are statistical in nature, so the material to be tested should be properly blended or mixed. An ideal mix is one in which all particles and constituents are distributed uniformly throughout the mixture. This condition is accomplished only through proper application of the variables involved in the mixing process, such as type of blender, volume of metal powder, rotational speed of the blender, and blending time (see the articles "Blending and Premixing of Metal Powders and Binders" and "Effect of Blending Techniques on Properties of Metal Powder Mixes" in this Volume).

Sampling and Classification of Powders

Terence Allen

Sampling of Powders

The object of sampling is to gain knowledge of the characteristics of the whole from measurements impracticable to apply to the whole: Bias, at any of the reduction stages, adversely affects the final analysis. Problems arise due to inhomogeneities in the parent distribution. If the bulk powder is homogeneous, or can be mixed prior to sampling in order to generate a homogeneous powder, sampling problems do not arise. Frequently it is not possible to mix the powder and a sampling campaign has to be prepared in order to obtain representative samples.

In order to establish homogeneity it is necessary to examine samples taken from the bulk, either at random or according to some predetermined pattern. If homogeneity is established, a single sample is representative of the bulk. The definition of homogeneity requires specification of the portions or sample sizes between which the variability is sufficiently small to be neglected.

The total sampling error is made up of errors due to the primary sampling, errors in subsequent sample dividing, and errors in the analysis itself. Sampling is said to be accurate when it is free from bias, that is, the error of sampling is a random variable about the true mean.

Two types of sampling errors are possible. Errors due to segregation of the bulk depend on the previous history of the powder and can be minimized by suitable mixing and building up a sample from a large number of increments.

Statistical errors cannot be prevented. Even for an ideal random mixture, the quantitative distribution in samples of a given magnitude is not constant but is subject to random fluctuations. This is the only sampling error that cannot be suppressed and occurs in ideal sampling. It can be estimated beforehand and reduced by increasing the sample size.

Samples are withdrawn from a population in order to estimate a certain characteristic of that population and to establish confidence limits for that characteristic. The characteristic may be particle size, composition, or quality; a measure of the spread of the distribution may also be required. The objective may be to set up limits between which the quality of a final product is acceptable, to decide whether the characteristics of a given lot meet preset criteria, or to estimate the variability within a lot or between lots.

If the material comes in containers, or can be viewed as discrete units, the objective may be to estimate the number of units outside of specification. The value of the estimate is largely dependent on the sampling technique adopted. It is of little value, and could impart false information, if it is biased or imprecise.

It is usually impossible to measure the size distribution of a bulk powder, so it is necessary to carry out measurements on a sample extracted from the bulk. This sample is itself frequently too large and has to be further subdivided. The stages in reducing from bulk to measurement samples are bulk or process stream (10³kg), gross sample (>kg), laboratory sample (<kg), test sample (g), and measurement sample (mg).

The gross sample can be one of a series of spot samples, which have been extracted in order to determine the variability of the bulk or process stream with location or time, or it can be made up of subsamples to be representative of the bulk as a whole. Historically the bulk sample has been obtained manually, but automatic inline sampling is becoming more common.

In some cases the gross sample is too large to send to the laboratory and has to be reduced in quantity. This reduction needs to be carried out in such a way that the laboratory sample is fully representative of the gross sample. When this reduction is unnecessary the gross sample is also the laboratory sample.

The laboratory sample may be required for a number of tests, so it is sometimes necessary to further subdivide it into test samples.

The test sample may be used in its entirety or further subdivided to form measurement and reference samples.

Powders may be classified as free-flowing or cohesive powders. Free-flowing powders tend to segregate during handling and storage, so spot samples are rarely representative. Cohesive powders tend to retain their characteristics during handling, so that if they are segregated during manufacture or packaging they will tend to remain segregated.

For these reasons it is recommended that, wherever possible, the *golden rules of sampling* should be followed:

- A powder should always be sampled when in motion.
- The whole of the stream of powder should be taken for many short increments of time, in preference to part of the stream being taken for the whole of the time.

Observance of these rules, coupled with an understanding of the manner in which segregation takes place, leads to the best sampling procedure. Any method that does not follow these rules should be regarded as a second-best method likely to lead to errors. Finally, the need or care and skill in abstracting samples cannot be overemphasized. There are a very large number of possible systems from which a gross sample has to be extracted, so it is impossible to lay down instructions that will address all situations. Essentially, the solution depends on whether the powder is stationary or moving and whether it is cohesive or free-flowing.

Sampling and Classification of Powders

Terence Allen

Sampling Stored Material

It is usual to assume that the powder was mixed before storage. If this assumption is not true, then the homogeneity of the powder will depend on its previous history. Thus, a nonflowing material that has been segregated during manufacture, or prior to storage, will remain segregated. For a free-flowing material, segregation can, and often does, occur during transfer from the mixer to the storage container.

Sampling Stored Nonflowing Material

Nonflowing material is a term for very fine cohesive powders, sticky material, moist material, or fibrous solids. These may be stored in small containers such as drums or bags, or in large containers such as trucks or railway wagons. Surface sampling is usually carried out with a scoop because of its simplicity: A presupposition is that the powder at the sampling point is representative of the bulk (i.e., that the powder was mixed before storage). Accuracy is increased by taking more than one sample, and the samples should be analyzed separately and combined in later analyses if the variation between samples is at an acceptable level.

Sampling Spears. Sampling accuracy is improved if samples from the body of the material are included, and this may be carried out with the aid of a sampling spear (thief). Three types are available (Fig. 1). Type 1 consists of an inner and outer tube with a closed end and longitudinal window so that the sampling chamber runs the full length of the spear; this generates a core sample. In type 2 the sampling chamber is at the end of the spear; this generates a spot sample. In type 3 there are separate chambers along the length of the spear; this generates several spot samples simultaneously. With a type 2 sampling spear it is usual to extract several samples at different depths, typically top, middle, and bottom, and blend these to obtain a composite sample. This procedure presupposes homogeneity within the container and should only be used when this assumption has been verified (i.e., the three samples should be analyzed separately a sufficient number of times to establish an acceptable level of statistical confidence).

Fig. 1 Sampling spears

The spear is thrust into the powder with the inner chamber closed off, and when in position the outer tube is rotated to allow powder to fall into the inner chamber. When the chamber is full, the inner tube is turned to the closed position and the spear is withdrawn. Possible segregation throughout the bed may be investigated with type 3, an average value for the length of the spear with type 2, and a spot sample with type 3. Frequently the spears are vibrated to facilitate filling, and this can lead to an unrepresentative quantity of fines entering the sample volume. The sampling chambers also have a tendency to jam if coarse particles are present, because they can get lodged between the inner and outer chambers.

Coning and Quartering. In industry it is common practice to sample small heaps by coning and quartering. The powder is formed into a heap, which is first flattened at the top and then separated into four equal segments with a sharp-edged board or shovel. The segments are drawn apart and, frequently, two opposite quadrants are recombined and the operation is repeated until a small enough sample has been generated. This practice is based on the assumption that the heap is symmetrical, and since this is rarely so, the withdrawn sample is usually nonrepresentative.

Sampling from Trucks or Wagons. Consignment sampling is carried out on a single consignment (e.g., a truck or wagon load). In sampling from a truck or a wagon it is recommended that eight samples be extracted (Ref 1). No increment should be taken at less than 12 in. below the surface; this avoids the surface layer, in which segregation can have occurred due to vibration (Fig. 2). Care needs to be taken to prevent powder sliding down the slope created due to removal of surface material.

Fig. 2 Sampling points for a wagon or a truck

Sampling Stored Free-Flowing Material. It is practically impossible to representatively sample stationary free-flowing powder because of the severe segregation that has almost certainly occurred. There is only one sound piece of advice to give regarding sampling such material: Don't! If there is no alternative, several samples should be taken and analyzed separately so that an estimate can be made of the degree of segregation.

Sampling from Containers. Suppose an analysis is required from several tons of material that is available in bags or small containers. Several of these containers should be selected systematically or, preferably, using a table of random numbers. The recommended number of samples depends on the number of containers (Table 1). The whole of each bag should then be sampled using a full stream or Vezin-type splitter so that the golden rules of sampling are obeyed. This is the only way to obtain a representative sample from each bag. Where this is not possible a sampling thief may be used. It is preferable to obtain a sample as the containers are being filled or emptied.

Table 1 Recommended number of containers to be sampled from a packaged lot

Number of containers in lot	Number of containers to be sampled
1-5	all
6-11	5
12-20	6
21-35	7
36-60	8
61-99	9
100-149	10
150-199	11
200-299	12
300-399	13

Note: For every additional 100 containers, one additional container should be sampled. Source: ISO 3954

Sampling and Classification of Powders

Terence Allen

Sampling Flowing Streams

Most powder systems are transported at some time during their manufacture as flowing streams: Hoppers are emptied by screw or belt conveyors, powders are transferred to bagging operations by screw or pneumatic conveyors, and many solids are transported through pipes. A general rule in all sampling is that whenever possible, the sample should be taken while the powder is in motion. This is usually easy with continuous processes; with consignment sampling it may be possible during filling and emptying of storage containers.

Sampling from a Conveyor Belt. When a sample is to be collected from a conveyor belt, the best position for collecting the increments is where the material falls in a stream from the end of the belt. If access at such a point is not possible, the sample must be collected from the belt. The whole of the powder on a short length of the belt must be collected. The particles at the edge of the belt may not be the same as those at the center, and particles at the top of the belt may not be the same as those at the bottom. If the belt can be stopped, the sample may be collected by inserting into the stream a frame consisting of two parallel plates shaped to fit the belt; the whole of the material between the plates is then swept out. A scoop can be used to scoop out an increment, but this operation can be hazardous if the belt is moving.

When sampling from a continuous stream, the sampling may be continuous or intermittent. In continuous sampling, a portion of the flowing stream is split off and frequently further divided subsequently. In intermittent sampling, the whole stream is taken for many short increments of time at fixed time intervals. These increments are usually compounded and samples for analysis are taken from this gross sample. Continuous sampling is deprecated because if there is segregation on the belt, the extracted sample may not be representative.

It is common practice, in sampling from a blender, to extract three samples: the first after the blender has been emptying for a few minutes, the second when the blender is half empty, and the third when the blender is almost empty. Note that blenders sometimes have a "heel" of unmixed material that is first out of the blender. Powder from the whole cross section of the blender discharge stream should be collected for each sample. This practice should only be used after the mixing efficiency of the blender has been established for each product by taking multiple samples and analyzing these separately.

Point Samplers. Samples can be extracted from the product stream by projecting a sample tube, containing a nozzle or orifice, into the flow. The particles impact the tube and fill the open cavity. The sampling head is out of the stream when not sampling. Snorkel-type samplers are available for vertical or inclined applications and can be preprogrammed for sampling frequency. It is not possible to sample nonhomogeneous streams representatively with this type of device. With the auger-type sampler, a slot inside the process stream is rotated to capture a cross section of the process stream, which is then delivered into a sample container. This type of device does not collect a representative sample unless the stream is homogeneous, and it has the added disadvantage that it obstructs flow.

Sampling from Falling Streams. In collecting from a falling stream of powder, care should be taken to offset the effects of segregation. Each increment should be obtained by collecting the whole of the stream for a short time. Care must be taken in putting the sampler in and out of the stream. Figure 3 shows correct and incorrect ways of doing this. Unless the time during which the receiver is stationary in its receiving position is long compared with the time taken to insert and withdraw the sampler, the method shown in Fig. 3(a) will lead to an excess of coarse particles, because the surface region of the stream, usually rich in coarse particles, is sampled for a longer time than the rest of the stream. The method shown in Fig. 3(b) is not subject to this objection. If this method is not possible due to some obstruction, the ratio of stationary to moving time for the receiver should be made as large as possible. In many cases it is not possible to collect the whole of the stream as this would give too large an amount to be handled. The best procedure in this case is to pass a sample collector of the form shown in Fig. 3(c) through the stream.

Fig. 3 Sampling from falling streams. (a) Bad sampling technique. (b) Good sampling technique. (c) Sampling procedure to be adopted for high mass flow rate

The width of the receiver, b , should be chosen to give an acceptable weight of sample but must not be made so small that the biggest particles have any difficulty in entering the receiver. Particles that strike the edges of the receiver are likely to bounce out and not be collected, so that the effective width is $(b-d)$, where d is the particle diameter. The effective width is therefore greater for small particles than for large ones. To reduce this error to an acceptable level, the ratio of receiver width to the diameter of the largest particle should be made as large as possible with a minimum value of 3:1. The depth, a , must be great enough to ensure that the receiver is never full of powder. If the receiver fills before it finishes its traverse through the powder, a wedge-shaped heap will form that is size selective. As more powder falls on top of the heap, the fine particles will percolate through the surface and be retained, whereas the coarse particles will roll down the sloping surface and be lost. The length of the receiver, c , should be sufficient to ensure that the full depth of the stream is collected.

Stream Sampling Ladles. Powder may be manually withdrawn from a moving stream of powder using one of the several commercially available ladles. These are suitable for occasional use, but automatic on-line stream sampling samplers are preferred for frequent applications.

Traverse Cutters. With large tonnages, samples taken from conveyors can represent large quantities of material that need to be further reduced. With the action shown in Fig. 4(a) and 4(b), uniform increments are withdrawn to give a representative sample, but with the action shown in Fig. 4(c), a biased sample results if the inner and outer arcs of the container are significantly different and the powder is segregated horizontally on the belt.

Fig. 4 Traversing cutters. (a) Straight path action, in line. (b) Cross line. (c) Oscillating or swinging arc path

Often, a traversing cutter is used as a primary sampler, and the extracted sample is further cut into a convenient quantity by a secondary sampling device. The secondary sampler must also conform with the golden rules of sampling.

A traversing cutter is satisfactory for many applications, but it has limitations that restrict its use:

- Although a traversing cutter is comparatively readily designed into a new plant, it is frequently difficult and expensive to retrofit an existing plant because of the space requirements.
- The quantity of sample obtained is proportional to product flow rate, and this can be inconvenient when the plant flow rate is subject to wide variations. On the other hand, where the daily average of a plant is required, this is a necessary condition.
- It is difficult to enclose the sampler to the extent required to prevent the escape of dust and fumes when handling dusty powders.

Sampling Dusty Material. Figure 5 shows a sampler designed to sample a dusty material, sampling taking place only on the return stroke. This is suitable provided that the trough extends the whole length of the stream and does not overflow. The radial cutter or Vezin sampler shown in Fig. 6 is suitable for sample reduction. These samples vary in size from a 15 cm laboratory unit to a 152 cm commercial unit.

Fig. 5 Full-stream trough sampler

Diverter Valve Sampler. The diverter valve shown in Fig. 7 is suitable for online intermittent sampling when there is limited head room. It can also be operated manually.

Fig. 7 Diverter valve sampler

Sampling and Classification of Powders

Terence Allen

Sample Reduction

The gross sample is frequently too large to be handled easily and may have to be reduced to a more convenient weight. Obviously, the method employed must conform with the two golden rules mentioned above. The amount of material to be handled is usually small enough that getting it in motion poses no great difficulty. There is a natural tendency to remove an aliquot with a scoop or spatula, and this must be avoided because it negates the effort involved in obtaining a representative sample from the bulk. Placing the material in a container and shaking it to obtain a good mix prior to extracting a scoop sample is not recommended.

To obtain the best results, the material should be made as homogeneous as possible by premixing. It is common practice then to empty the material into a hopper, and this should be done with care. A homogeneous segregating powder will segregate when fed to a hopper from a central inlet, because in essence it is being poured into a heap. In a core flow hopper the central region (which, with improper feeding, will be rich in fines) empties first, followed by the material nearer the walls, which has an excess of coarse particles. The walls of the hopper should have steep sides (at least 70°) to ensure mass flow, and the hopper should be filled in such a way that size segregation does not occur. This can best be done by moving the pour point about so that the surface of the powder is more or less horizontal. Several sample-dividing devices are discussed briefly below.

Scoop sampling consists of plunging a scoop into the powder and removing a sample. This method is particularly prone to error because the whole of the sample does not pass through the sampling device, and because the sample is taken from the surface, where it may not be representative of the mass. For powder in a container, it is usual to shake the sample prior to sampling in an attempt to achieve a good mix. However, the method of shaking can promote segregation.

Coning and quartering consists of pouring the powder into a heap and relying on its radial symmetry to give identical samples when the heap is flattened and divided by a cross-shaped cutter. This method is no more accurate than scoop or

thief sampling, which are simpler to carry out, but gross errors are to be expected. Coning and quartering should never be used with free-flowing powders.

Table Sampling. In a sampling table the material is fed to the top of an inclined plane in which there is a series of holes. Prisms placed in the path of the stream break it into fractions. Some powder falls through the holes and is discarded, while the powder remaining on the plane passes on to the next row of holes and prisms, and more is removed, and so on. The powder reaching the bottom of the plane is the sample. The objection to this type of device is that it relies on the initial feed being uniformly distributed, and on a complete mixing after each separation, and in general these conditions are not achieved. As it relies on the removal of part of the stream sequentially, errors are compounded at each separation, hence its accuracy is low.

Chute Splitting. The chute splitter consists of a V-shaped trough, along the bottom of which is a series of chutes that alternately feed two trays placed on either side of the trough. The material is repeatedly halved until a sample of the desired size is obtained. When carried out with great care this method can give satisfactory sample division, but it is particularly prone to operator error, which is detectable by unequal splitting of the sample.

The above methods are all popular because the samplers contain no moving parts and are consequently inexpensive.

Rotatory Sample Divider. The rotary sample divider conforms to the golden rules of sampling. The preferred method of using this device is to fill a mass flow hopper in such a way that segregation does not occur. The table is then set in motion and the hopper outlet is opened so that the powder falls into the collecting boxes. The use of a vibratory feeder is recommended to provide a constant flow rate. Several versions of this instrument are available, some of which were designed for free-flowing powders, some for dusty powders, and some for cohesive powders. They handle quantities from 40 L down to a few grams.

Sampling and Classification of Powders

Terence Allen

Slurry Sampling

Slurry process streams vary in flow rate, solids concentration, and particle size distribution. Any sampling technique must be able to cope with these variations without affecting the representativeness of the extracted sample. For batch sampling, automatic devices are available where a sampling slot traverses intermittently across a free-falling slurry. Unfortunately, it is difficult to improvise with this technique for continuous sampling, because such samplers introduce pulsating flow conditions into the system.

Sampling and Classification of Powders

Terence Allen

Evaluation of Sampling

Experimental tests of sampling techniques are compared in Table 2 as an example. Binary mixtures of coarse and fine sand (60:40 ratio) were examined (Ref 2) using various laboratory sampling techniques. In every case, 16 samples were examined to give the standard deviations shown in column 2. It may be deduced that very little confidence can be placed in the first three techniques and that the rotary sample divider is so superior to all other methods that it should be used whenever possible.

Table 2 Reliability of selected sampling methods using a 60:40 sand mixture

Sampling technique	Standard deviation, %
Coning and quartering	6.81
Scoop sampling	5.14
Table sampling	2.09
Chute slitting	1.01
Rotary sample dividing	0.146
Random variation	0.075

Sampling and Classification of Powders

Terence Allen

Weight of Sample Required

Gross Sample. Analyses are carried out on a sample extracted from the bulk, which, irrespective of the precautions taken, never represents the bulk exactly. The limiting (minimum) weight of the gross sample may be calculated, using a simple formula to give an error within predesignated limits, provided that the weight of the gross sample is much smaller than that of the bulk. The limiting weight is given by:

$$M_s = \frac{1}{2} \left(\frac{\rho}{\sigma_i^2} \right) \left(\frac{1}{w_1} - 2 \right) d_1^3 \times 10^3 \quad (\text{Eq 1})$$

where M_s is the limiting weight in grams, ρ is the powder density in $\text{g} \cdot \text{cm}^{-3}$, σ_i^2 is the variance of the tolerated sample error, w_1 is the fractional mass of the coarsest size class being sampled, and d_1^3 is the arithmetic mean of the cubes of the extreme diameter in the size class in cubic centimeters. This equation is applicable when the coarsest class covers a size range of not more than $\sqrt{2:1}$ and w_1 is less than 50% of the total sample. Table 3 gives sample values.

Table 3 Minimum sample mass required for sampling from a stream of powder

Upper sieve size, μm	Lower sieve size, μm	Mass % in class ($100w_1$)	Sample weight required, g
600	420	0.1	37,500
420	300	2.5	474
300	212	19.2	14.9
212	150	35.6	1.32

Sample by Increments. For sampling a moving stream of powder, the gross sample is made up of increments. In this case the minimum incremental weight is given by:

$$M_i = \frac{\mu_0 w_0}{v_0} \quad (\text{Eq 2})$$

where M_i is the average mass of the increment, μ_0 is the average rate of flow, w_0 is the cutter width for a traversing cutter, and v_0 is the cutter velocity. If w_0 is too small, a biased sample deficient in coarse particles, results. For this reason w_0 should be at least $3d$, where d is the diameter of the largest particle present in the bulk.

ISO 3081 suggests a minimum incremental mass based on the maximum particle size in millimeters. These values are given in Table 4. Secondary samplers then reduce this to analytical quantities.

Table 4 Minimum incremental mass required for sampling from a stream of powder

Maximum particle size, mm	Minimum mass of increment, kg
250-150	40.0
150-100	20.0
100-50	12.0
50-20	4.0
20-10	0.8
10-0	0.3

Gy (Ref 3) proposed an equation relating the standard deviation, which he calls the fundamental error σ_F , to the sample size:

$$\sigma_F^2 = \left(\frac{1}{w} - \frac{1}{W} \right) C d^3 \quad (\text{Eq 3})$$

where W is the mass of the bulk; $w = n\omega$ is the mass of n increments, each of weight ω , that make up the sample; C is the heterogeneity constant for the material being sampled; and d is the diameter of the coarsest element.

For the mining industry (Ref 3), Gy expressed the constant C in the form $C = clfg$ where:

$$C = \frac{1-P}{P} \rho \quad (\text{Eq 4})$$

P is the investigated constant. ρ is the true density of the material. l is the relative degree of homogeneity where for a random mixture $l = 1$, and for a perfect mixture $l = 0$. f is a shape factor assumed to be equal to 0.5 for irregular particles and 1 for regular particles. g is a measure of the width of the size distribution where $g = 0.25$ for a wide distribution and $g = 0.75$ for a narrow distribution (i.e., $d_{\max} < 2d_{\min}$).

For the pharmaceutical industry, Deleuil (Ref 4) suggested $C = 0.1lc$ with the coarsest size being replaced by the 95% size.

For $W \gg w$, Eq 4 can be written:

$$w\theta^2 = 0.1l \left(\frac{1-P}{P^3} \right) \rho r^3 d^3 \quad (\text{Eq 5})$$

where $\theta = t(\sigma_F/P)$ and $t = 3$ (99.9% confidence level) for total quality.

- For $d_{95} = 100 \mu\text{m}$, $\rho = 1.5$, $P = 10^{-3}$ (1000 ppm), $\theta = 0.2$, $l = 0.03$ (random), and $w = 1000$ g.
- For $d_{95} = 100 \mu\text{m}$, $\rho = 1.5$, $P = 0.05$, $\theta = 0.05$, $l = 1$ (homogeneous), and $w = 4$ g.
- For $d_{95} = 20 \mu\text{m}$, $\rho = 1.5$, $P = 10^{-4}$ (100 ppm), $\theta = 0.05$, $l = 0.03$ (random), and $w = 8000$ g.

Sampling and Classification of Powders

Terence Allen

Powder Classification

Classification methods are used to obtain particular powder distributions or to exclude certain powder sizes from a distribution. The general process for separating dispersed materials is known as "air classification" or "fluid classification," where powder classification is based on the movement of the suspended particles at different points under the influence of a force. The fluid is usually water or air, and the field force may involve gravity or centrifugal or coriolis forces. The other forces of importance are the drag forces due to the relative flow between the particles and the flow medium, and the inertia forces due to accelerated particle movement. The classification process is defined in terms of sorting and sizing. The former includes processes such as froth flotation, where particles are separated on the basis of chemical differences and particle density. The latter, which is covered here, is based only on differences in particle size.

In an ideal system the cut size is well defined and there are no coarse particles in the fine fraction, and vice versa. In practice, however, there is always overlapping of sizes. The cut size may be predicted from theory, but this usually differs from the actual cut size due to the difficulty of accurately predicting the flow pattern in the system. It is therefore necessary to be able to predict the future performance of classifiers based on their past performance.

Sampling and Classification of Powders

Terence Allen

Basic Variables

Consider a single stage of a classifier where W , W_c , and W_f are the weights of the feed, coarse stream, and fine stream, respectively; $F(x)$, $F_c(x)$, and $F_f(x)$ are the cumulative fraction undersize of feed, coarse stream, and fine stream, respectively; and x is particle size. Then:

$$W = W_c + W_f \quad (\text{Eq 6})$$

$$W \frac{dF(x)}{dx} = W_c \frac{dF_c(x)}{dx} + W_f \frac{dF_f(x)}{dx} \quad (\text{Eq 7})$$

The total fine efficiency may be defined as:

$$E_f = \frac{W_f}{W} \quad (\text{Eq 8})$$

and the total coarse efficiency as:

$$E_c = \frac{W_c}{W} \quad (\text{Eq 9})$$

so that $E_f + E_c = 1$. The total efficiency has no value in determining the effectiveness of a classification process, because it only defines how much of the feed ends up in one or other of the two outlet streams, not how much of the desired material ends up in the correct outlet stream. To discover this, it is necessary to determine the grade efficiency, which is independent of the feed, provided that the classifier is not overloaded:

Grade efficiency at size x =

$$\frac{\text{Amount of desired material in product of size } x}{\text{Amount of desired material in feed of size } x} \quad (\text{Eq 10a})$$

Coarse grade efficiency, $G_c(x)$, at size x =

$$\frac{\text{Amount of coarse product of size } x}{\text{Amount of feed of size } x} \quad (\text{Eq 10b})$$

$$G_c(x) = W_c \frac{dF_c(x)}{dx} + W \frac{dF(x)}{dx} \quad (\text{Eq 10c})$$

$$G_c(x) = \frac{W_c}{W} \frac{dF_c(x)}{dF(x)} \quad (\text{Eq 10d})$$

$$G_c(x) = E_c \frac{dF_c(x)}{dx} \quad (\text{Eq 10e})$$

Similarly, the fine grade efficiency is defined as:

$$G_f(x) = \frac{W_f}{W} \frac{dF_f(x)}{dF(x)} \quad (\text{Eq 11a})$$

$$G_f(x) = E_f \frac{dF_f(x)}{dx} \quad (\text{Eq 11b})$$

Hence, from Eq 7, 10, and 11:

$$G_c(x) = 1 - G_f(x) \quad (\text{Eq 12})$$

These equations can be used to evaluate the grade efficiency of a classifier, provided that the total efficiency and the size distribution of two of the streams are known. Results are usually plotted as grade efficiency curves of $G_c(x)$ or $G_f(x)$ against x . The classifier separates on the basis of Stokes diameter, so it is preferable to carry out the size determinations on the same basis.

The grade efficiency curve is best determined by plotting $F_c(x)$ against $F(x)$ and differentiating (Fig. 8b), because this allows experimental errors to be smoothed out. The tangent at $F_c(x) = 100\%$ in Fig. 8(b) has a slope of $dF_c(x)/dF(x) = 100/60$; hence, $E_c = 60/100$. Because this tangent merges with the curve at $x = 58 \mu\text{m}$, all particles coarser than $58 \mu\text{m}$ are collected with the coarse fraction. Differentiating this curve at selected values of $F(x)$ and multiplying by 60 gives $G_c(x)$, the relevant diameters being determined from size distribution data. The 50% size on the grade efficiency curve is called the *equiprobable* size because particles of this size have an equal chance of being in either the coarse or the fine stream. Figure 8(a) shows how the feed is split between the coarse and fine fractions, i.e., $F_f(x) + F_c(x) = F(x)$.

(a)

(b)

(c)

Fig. 8 Graphical determination of grade efficiency curve

The grade efficiency is often expressed as a single number. This number is known as the sharpness index, ψ , and is a measure of the slope of the grade efficiency curve:

$$75\psi_{25} = \frac{x_{75}}{x_{25}} \quad (\text{Eq 13})$$

where x_{75} and x_{25} are the particle sizes at which the grade efficiency is 75% and 25%, respectively. For perfect classification $\psi = 1$, while values above 3 are considered poor. Alternatively $10\psi_{90}$ has been used.

These ratios are not always adequate to define the sharpness of cut. In many cases it is important to keep the amount of fines in the coarse or the amount of coarse in the fines as small as possible. For these cases a measure of the effectiveness of a separation process is given by the following for the coarse yield:

$$\psi_c = \frac{\text{Weight of particles coarser than } e \text{ in the coarse fraction}}{\text{Weight of particles coarser than } e \text{ in the feed}} \quad (\text{Eq 14a})$$

$$\psi_c = E_c \frac{\sum_{x_{\max}}^e F_c(x)}{\sum_e F(x)} \quad (\text{Eq 14b})$$

Similarly, for the fine yield:

$$\psi_f = E_f \frac{\sum_{x_{\min}}^e F_c(x)}{\sum_e F(x)} \quad (\text{Eq 15})$$

Sampling and Classification of Powders

Systems for Powder Classification

Classifiers may be divided into two categories: counterflow equilibrium and crossflow separation.

Counterflow can occur in either a gravitational or centrifugal field. The field force and the drag force act in opposite directions and particles leave the separation zone in one of two directions according to their size. At the "cut" size, particles are acted on by two equal and opposite forces; hence, they stay in equilibrium in the separation zone. In gravitational systems these particles remain in a state of suspension, while in a centrifugal field the equilibrium particles revolve at a fixed radius, which is governed by the rate at which material is withdrawn from the system. They would therefore accumulate to a very high concentration in a continuously operated classifier, if they were not distributed to the coarse and fine fractions by a stochastic mixing process.

In a crossflow classifier, the feed material enters the flow medium at one point in the classification chamber, at an angle to the direction of fluid flow, and is fanned out under the action of field, inertia, and drag forces. Particles of different sizes describe different trajectories and so can be separated according to size.

Counterflow Equilibrium Classifiers in a Gravitational Field: Elutriators. Elutriation is a process of grading particles by means of an upward current of fluid, usually air or water. The grading is carried out in one or a series of containers, the bodies of which are cylindrical and the bases of which are inverted cones. The cut size is changed by altering the volume flow rate and the cross-sectional areas of the elutriation chambers. The flow medium is usually air, although water is used occasionally.

In air elutriators, air containing particles sweep up through the system at a preset flow rate. Particles with a settling velocity lower than the air flow rate are carried out with the air stream, whereas larger particles are retained in the

elutriation chamber. The separation is very slow but can be speeded up by the use of zig-zag classifiers, which act as a succession of elutriators in series.

Zig-Zag Classifiers. Several versions of the zig-zag classifiers are available (Fig. 9). These may be categorized as gravitational or centrifugal counterflow classifiers. A feed rating worm (b) feeds the unclassified material (c) into a classifying chamber. Radially arranged blades on the outer face of the classifier rotor (d) speed the inflow of material up to the peripheral velocity of the rotor suspending it, extra air being admitted through (e). The dust-air mixture is then sucked in to the zig-zag-shaped rotor channels where classification takes place (Fig. 10). Fine material is sucked into the classifier center (g), where it leaves via a cyclone. The coarse material (f) is expelled by centrifugal force. At the periphery it is flushed by the incoming air before being discharged. Gravitational instruments operate in the 1 to 100 μm size range, centrifugal instruments from 0.1 to 6 μm .

Fig. 9 The Alpine zig-zag centrifugal laboratory classifier

Fig. 10 Mode of action of a zig-zag classifier. The small balls are the fine material; the large balls are the coarse material. Bolts indicate the material guide motion

Cross-flow gravitational classification is performed with the Warmain Cyclosizer (Ref 5), which is a hydraulic cyclone elutriator (Fig. 11). Using inverted cyclones as separators with water as the flow medium, samples of between 25 to 200 g are reduced to five fractions having cut sizes (for quartz) of 44, 33, 15, and 10 μm . The cyclones are arranged in series, and during a run the oversize for each cyclone is trapped and subjected to elutriating action for a fixed time period. At the end of a run the trapped materials are extracted by opening the valves at the apex of each cyclone in turn, and after decantation, the solids are recovered by filtration and evaporation.

Fig. 11 Principle of the Warmain Cyclosizer

Counterflow Centrifugal Classifiers. The Bahco Classifier is a centrifugal elutriator (Fig. 12). The sample is introduced into a spiral air current created by a hollow disc rotating at 3500 rpm. Air and dust are drawn through the cavity in a radially inward direction against centrifugal forces. Separation into different size fractions is made by altering the air velocity, which is effected by changing the air inlet gap by the use of spacers. Instrument calibration is necessary. For the sample, 5 to 10 g of powder are required, which can be graded in the size range 5 to 100 μm .

Fig. 12 Simplified schematic diagram of the Bahco microparticle classifier. 1, electric motor; 2, threaded spindle; 3, symmetrical disk; 4, sifting chamber; 5, container; 6, housing; 7, top edge; 8, radial vanes; 9, feed point; 10, feed hole; 11, rotor; 12, rotary duct; 13, feed slot; 14, fanwheel outlet

Crossflow Centrifugal Classifiers. The principle of a crossflow centrifugal laboratory classifier is illustrated in Fig. 13. A vaned rotor produces a centrifugal field, while at the same time air is drawn into the center of the rotor. All but about 5% of the air intake, induced by a positive displacement pump downstream of the classifier, enters the classification zone through a very narrow gap formed between the rotor and the stator. This leads to a very high turbulence in the preclassification zone. The material enters the classifier through a venturi-type nozzle with the remaining 5% of air. Between planes 1 and 2 the ratio of centrifugal force to drag force is kept very nearly constant by a diverging radial cross section. This zone is the classification zone. The smaller particles are carried out through the middle and the larger ones move toward the stator, where they undergo disaggregation until they reach the exit. The cut size of these machines ranges from 0.5 to 50 μm .

Fig. 13 A cross-flow centrifugal laboratory classifier

Crossflow Elbow Classifier. In the cross-flow air classifier (Fig. 14) the main air is introduced at a_1 and secondary air at a_2 . Both streams are bent around a solid wall (b), and the resulting flow follows the bend without leaving the wall or forming vortices. The so-called Coanda effect helps to maintain the flow around the bend for approximately 90° , and this is enhanced by the application of suction.

Fig. 14 Principle of the cross-flow elbow classifier

Sieving Methods

Sieving methods are used to obtain particular powder distributions or to obtain narrow size ranges of a powder. Sieving is a particularly useful procedure because particles are sorted into categories solely on the basis of size, independently of other properties (density, surface, etc.). It can be used to classify dry or wet powders and generates narrowly classified fractions. With micromesh sieves, near-monodisperse powders can be generated in the range of 1 to 10 μm .

Sieving consists of placing a powder sample on a sieve containing openings of a fixed size and agitating the sieve in such a way that particles that can pass through the openings do so. To speed up the analysis, several sieves are stacked on top of each other, with the sieve containing the coarsest openings on top. This "nest" of sieves is vibrated until the residue on each sieve contains particles that could pass through the upper sieve but not through the lower sieve.

A variety of sieve apertures are currently available, ranging in size from about 20 μm to millimeters for woven wire sieves, down to 5 μm or less for electroformed sieves, and greater than 1 mm for punched plate sieves. Woven wire sieves generally have pseudosquare apertures (i.e., the weaving process generates trapezoidal apertures in three dimensions), but punched plate and electroformed sieves are available with round and rectangular apertures. A variety of other shapes are also readily available.

Sieve analysis presents three major difficulties. With woven wire sieves the weaving process produces three-dimensional apertures with considerable tolerances, particularly for fine-woven mesh (Ref 2). The mesh is easily damaged in use (Ref 3). The particles must be efficiently presented to the sieve apertures.

Fractionation by sieving is a function of two dimensions only, maximum breadth and maximum thickness, because unless the particles are excessively elongated, the length does not affect the passage of particles through the sieve apertures (Fig. 15). Particles having two dimensions smaller than the openings will pass through when the sieve is vibrated, whereas larger particles will be retained. The sieve size d_A is defined, on the basis of woven wire sieves, as the minimum square aperture through which a particle can pass.

Fig. 15 Sieved size of an irregularly shaped particle

The sieve surface consists of a go/no-go barrier: particles much smaller in size pass through rapidly, and larger particles pass through more slowly. The apertures have a range of sizes, so the final particle that can pass through will pass through

the largest opening when its two smaller dimensions are in a preferred direction. Because this takes a very long time, sieving is usually deemed complete when not more than 0.2% of the original weight of sample passes through in a 2 min sieving operation (Ref 6).

Sieves are often referred to by their mesh size, which is the number of wires per linear inch. American Society for Testing Materials standards range from 635 mesh (20 μm) to 5 mesh (125 mm). The apertures for the 400 mesh are 37.5 μm ; hence, the wire thickness is 26 μm and the percentage open area is 35.

Sieve analyses can be highly reproducible even when different sets of sieves are used. Although most of the problems associated with sieving have been known for many years and solutions have been proposed, reproducibility is rarely achieved in practice due to failure to recognize these problems (Ref 7).

Sampling and Classification of Powders

Terence Allen

Sieve Types

Woven-Wire and Punched Plate Sieves. Sieve cloth is woven from wire, and the cloth is soldered and clamped to the bottom of cylindrical containers (Ref 8). Although the apertures are described as square, they deviate from this shape due to the three-dimensional structure of the weave. Heavy-duty sieves are often made of perforated plate, giving rise to circular holes (Ref 9). Various other shapes, such as slots for sieving fibers, are also available. Fine sieves are usually woven with phosphor bronze wire, medium sieves with brass, and coarse sieves with mild steel. Special-purpose sieves are also available in stainless steel, and the flour industry uses nylon or silk. A variety of electroformed sieves are also available.

The cylindrical sieve cloth containers (sieves) are formed in such a way that they will stack, one on top of another, to give a snug fit (Fig. 16).

Fig. 16 Stacked sieves on a shaker with rotary and tapping action

A variety of sieve aperture ranges are currently used, and these may be classified as coarse (4 to 100 mm), medium (0.2 to 4 mm), and fine (less than 0.2 mm). The fine range extends down to 20 μm with woven wire mesh and to 5 μm or less with electroformed sieves.

Large-scale sieving machines, to take a charge of 50 to 100 kg, are needed for the coarse range. A wide range of commercial sieve shakers are available for the medium range, and these usually classify the powder into five or six fractions with a loading of 50 to 100 g. Special sieving techniques are used with the finer micromesh sieves.

Due to the method of manufacture, woven wire sieves have poor tolerances, particularly as the aperture size decreases. Tolerances are improved and the lower size limit is extended with the electroformed micromesh sieves.

Electroformed Micromesh Sieves. Micro-mesh sieves (Ref 10), generated by a photoetching process, are available in a wide range of sizes and aperture shapes.

Basically, the photoetching process is as follows. A fully degreased metal sheet is covered on both sides with a photosensitive coating and the desired pattern is applied photographically to both sides of the sheet. Subsequently the sheet is passed through an etching machine and the unexposed metal is etched away. Finally, the photosensitive coating is removed. A supporting grid is made by printing a coarse line pattern on both sides of a sheet of copper foil coated with photosensitive enamel. The foil is developed and the material between the lines is etched away. The mesh is drawn tautly over the grid and nickel plated onto it. The precision of the method gives a tolerance of 2 μm for apertures from 300 to 500 μm reducing to 1 μm for apertures from 5 to 106 μm . For square mesh sieves the pattern is ruled onto a wax-coated glass plate with up to 8000 lines per inch, with each line 0.0001 in. wide, and the grooves are etched and filled. The lower limit for off-the-shelf sieves is about 5 μm but apertures down to 1 μm have been produced. Apertures are normally square or round. The percentage of open area decreases with decreasing aperture size, ranging from 2.4% for 5 μm aperture sieves to 31.5% for 40 μm aperture sieves. This leads to greatly extended sieving time when the smaller aperture sieves are used.

Some round aperture sieves have apertures in the shape of truncated cones with the small circle uppermost. This reduces blinding but also reduces the open area and therefore prolongs the sieving time. When sturdier thicker sieves are required, they are subjected to further electrodeposition on both sides to produce biconical apertures.

The tolerances with micromesh sieves are much better than those for woven-wire sieves, the apertures being guaranteed to $\pm 2 \mu\text{m}$ of nominal size except for the smaller-aperture sieves. Each type of sieve has advantages and disadvantages; for example, sieves having a large percentage of open area are structurally weaker but measurement time is reduced.

Size and shape accuracy are improved by depositing successive layers of nickel and copper on a stainless steel plate, followed by etching through a photolithographic mask additional layers of copper and nickel. The holes are filled with dielectric, after which the additional nickel is removed down to the copper layer.

Dry sieving is often possible with the coarser micromesh sieves, and this may be speeded up, and the lower limit extended, with air jet and sonic sifting. Agglomeration of the particles can sometimes be reduced by drying or adding about 1% of a dispersant such as stearic acid or fumed silica. If this is unsuccessful, wet methods may have to be used.

Ultrasonics are frequently used as an aid to sieving or for cleaning blocked sieves. The delicate mesh can be ruptured under these conditions, and this readily occurs at low frequencies. The rate of cavitation is less in hydrocarbons than in alcohol and about six times greater in water than in alcohol. Saturating the alcohol with carbon dioxide reduces the rate. An upper limit of 40 kHz and a power level of 40 W is recommended. Still higher frequencies reduce the amount of erosion. ASTM E 161-70 recommends cleaning sieves, 15 to 20 s at a time, with a low-power 40 kHz ultrasonic bath containing an equivolume mixture of isopropyl or ethyl alcohol and water with the sieve in a vertical position.

Standard Sieves. The United States Standard Sieve Series described by ASTM (Ref 8) ranges from 20 μm to 5 in. According to ASTM, the nominal 75 μm sieve has a median aperture size in the range of 70 to 80 μm , and not more 5% of the apertures shall fall in the intermediate to maximum size range of 91 to 103 μm . This implies that there is a probability of having a 103 μm aperture in a nominal 75 μm sieve. It is clear that oversize apertures are more undesirable than undersize ones, because the latter are merely ineffective while the former permit the passage of oversize particles. The relative tolerance increases with decreasing nominal size, leading to poor reproducibility when analyses are carried out using different nests of uncalibrated sieves. Electroformed sieves with square or round apertures and tolerances of $\pm 2 \mu\text{m}$ are also available.

Complete instructions and procedures on the use and calibration of testing sieves are contained in Ref 11. This publication also contains a list of all published ASTM standards on sieve analysis procedures for specific materials or industries. Standard frames are available with nominal diameters of 3, 6, 8, 10, or 12 in. Nonstandard frames are also available.

Most test sieves are certified and manufactured to ISO 9002 standards. Woven-wire sieves, having apertures ranging from 20 μm to 125 mm, are readily available in 100, 200, 300, and 450 mm diameters as well as 3, 8, 12, and 18 in. diameters. Microplate sieves are available in 100 and 200 mm diameters with round or square apertures ranging from 1 to 125 mm.

Micromesh electroformed sieves are available in 3, 8, and 12 in. diameter frames, as well as custom-made sizes. Sieves have apertures ranging from 5 to 500 μm , and other apertures are available. Etched sieves have round apertures ranging from 500 to 1200 μm .

Sampling and Classification of Powders

Terence Allen

Process Variables

End Point of the Sieving Process. The nominal wire thickness for a 75 μm sieve is 52 μm . Hence, at the commencement of a sieving operation, the nominal open area comprises 35% of the total area [i.e., $(75/127)^2$], with apertures ranging in size from 42 to 108 μm (Fig. 17). As sieving progresses, the number of particles that can pass through the smaller aperture decreases, as well as the percentage of available open area. At the same time the effective sieve size increases, rising, in the example given above, to 84 μm , then to 94 μm , and eventually to the largest aperture in the sieve cloth. Thus, the mechanism of sieving can be divided into two regions with a transition region in between: an initial region that relates to the passage of particles much finer than the mesh openings, and a second region that relates to the passage of near-mesh particles (Fig. 18). Near-mesh particles are defined as particles that will pass through the sieve openings in only a limited number of ways, and the ultimate particle is the one that will pass only through the largest aperture in only one orientation.

Fig. 17 Effective aperture width distribution with increasing sieving time

Fig. 18 The rate at which particles pass through a sieve

The end point of sieving should be selected at the beginning of region 2. This can be done by plotting the time-weight curve on log-probability paper and selecting the end point. It is difficult to do this in practice, and an alternative procedure is to use a log-log plot and define the end point as the intersection of the extrapolation for the two regions (Fig. 18).

Using the conventional rate test, the sieving operation is terminated sometime during region 2. The true end point, when every particle capable of passing through a sieve has done so, is not reached unless the sieving time is unduly protracted.

Near-mesh particles are defined as particles that pass through the sieve openings in only a limited number of ways relative to the many possible orientations with respect to the sieve surface. The passage of such particles is a statistical process; that is, there is always an element of chance as to whether a particular particle will or will not pass through the sieve. In

the limit, the sieving process is controlled by the largest aperture through which the ultimate particle will pass in only one particular orientation. In practice there is no end point to a sieving operation, so this is defined in an arbitrary manner.

The rate method is fundamentally more accurate than the time method, but it is more tedious to apply in practice, and for most routine purposes a specified sieving time is adequate.

Conventional dry sieving is not recommended for brittle material because attrition takes place and an end point is difficult to define. The rate of passage of particles may fail to decrease with sieving time due to particle attrition, particle deagglomeration, or a damaged sieve.

Calibration of Sieves. It is not widely realized that analyses of the same sample of material by different sieves of the same nominal aperture size are subject to discrepancies, which may be considerable. These discrepancies may be due to nonrepresentative samples, differences in the amount of time the material is sieved, operator errors, humidity, different sieving actions, and differences in the sieves themselves.

Ideally, sieves should have apertures of identical shape and size. However, due to the methods of fabrication, woven-wire sieves have a range of aperture sizes and weaving gives a three dimensional effect. Fairly wide tolerances are accepted and specified in standards, but even these are sometimes exceeded in practice. In order to obtain agreement between different sets of sieves it is therefore necessary to calibrate them and thenceforth to monitor them to detect signs of wear.

One way of standardizing a single set of sieves is to analyze the products of comminution. It is known that the products are usually log-normally distributed; hence, if the distribution is plotted on a log-probability paper a straight line should result. The experimental data are fitted to the best straight line by converting the nominal sieve aperture to an effective sieve aperture.

The traditional method of determining the median and spread of aperture sizes for a woven-wire sieve is to size a randomly selected set of apertures using a microscope. Due to the method of manufacture the measurements for the warp and weft will tend to differ. The limiting size may also be determined by using spherical particles. These are fed onto the sieve, the sieve is shaken, and the excess is removed. Many spheres will have jammed into the sieve cloth and may be removed for microscopic examination.

Sieves may be monitored using glass beads, available from the National Bureau of Standards, every few months to find out whether the sieve apertures are deteriorating or enlarging. The whole sample is placed on the sieves and shaken in the manner in which tests will be made on test samples. The percentage retained on each sieve is determined and the effective opening on each sieve is determined from calibration data supplied with the bead set. Standard polystyrene spheres are also available for calibration purposes from laboratory supplies (such as Gilson and Duke Standards).

Sieves may also be calibrated by a counting and weighing technique applied to the fraction of particles passing the sieve immediately prior to the end of an analysis. These will have a very narrow size range and the average particle size may be taken as the cut size of the sieve. A minimum number (n) of particles need to be weighed to obtain accurate volume diameters (d_v). Let this weight be m and the particle density be ρ , then:

$$d_v = \left(\frac{6m}{\rho n} \right)^{1/3} \quad (\text{Eq 16})$$

Particles larger than 250 μm can be easily counted by hand and, if weighed in batches of 100, d_v is found to be reproducible to three significant figures. For particles between 100 and 250 μm , it is necessary to count in batches of 1000 using a magnifier. For sizes smaller than this the Coulter principle can be used to obtain the number concentration in a known suspension. Sieve analyses are then plotted against volume diameter in preference to the nominal sieve diameter. The method is tedious and time consuming, and the Community Bureau of Reference in Brussels has prepared quartz samples by this method for use as calibration material. The quartz is fed to a stack of sieves, and the analytical cut size is read off the cumulative distribution curve of the calibration material.

Sieving Errors. Hand sieving is the reference technique by which other sieving techniques should be judged. For instance, the French standard NFX 11-57 states: "If sieving machines are used, they must be built and used in such a way that the sieve analysis must, within the agreed tolerances, agree with the analysis obtained by hand sieving."

The apertures of a sieve may be regarded as a series of gages that reject or pass particles as they are presented at the aperture. The probability that a particle will present itself to an aperture depends on:

- *The particle size distribution of the powder.* The presence of a large fraction of near-mesh particles reduces the sieving efficiency. An excess of fines has the same effect.
- *The number of particles on the sieve (load).* The smaller the sieve loading, the more rapid the analysis. Too low a load, however, leads to errors in weighing and unacceptable percentage losses.
- *The physical properties of the particles.* These include adhesion and other surface phenomena.
- *The method of shaking the sieve.* Sieve motion should minimize the risk of aperture blockage and preferably include a jolting action to remove particles that have wedged in the sieve mesh.
- *Particle shape.* Elongated particles sieve more slowly than compact particles.
- *The geometry of the sieving surface* (e.g., the fractional open area). Whether or not the particle will pass the sieve when it is presented at the sieving surface will depend on its dimensions and the angle at which it is presented.

The size distribution given by the sieving operation also depends on:

- Duration of sieving
- Variation of sieve aperture
- Wear
- Errors of observation and experiment
- Errors of sampling
- Effect of different equipment and operation

It is evident that a reduction in sieve loading is more effective than prolonging the sieving. It is therefore recommended that the sample should be as small as is compatible with convenient handling. Although differences between analyses are inevitable, standardization of procedure more than doubles the reproducibility of a sieving operation. Sieve calibration increases this even further.

Sampling and Classification of Powders

Terence Allen

Methods of Sieving

Large-scale sieving machines, requiring a charge of 50 to 100 kg of powder, are used for the coarsest size range. A range of commercial sieve shakers are available for medium-sized-aperture sieves, and they usually classify the powder into five or six fractions, with a charge of 50 to 100 g.

Dry sieving is used for coarse separation, but other procedures are necessary as the powder becomes finer and more cohesive. Machine sieving is performed by stacking sieves in ascending order of aperture size and placing the powder on the top sieve. The most aggressive action is performed with Pascal Incluno and Tyler Ro-tap sieves, which combine gyrating and jolting movements, although a simple vibratory action may be suitable in many cases. Automatic machines use an air jet to clear the sieves or ultrasonics to effect passage through the apertures. The sonic sifter combines two actions, a vertically oscillating column of air and a repetitive mechanical pulse. Wet sieving is frequently used with cohesive powders.

Amount of Sample Required. In determining the amount of sample to be used, it is necessary to consider the type of material, its sievability, and the range of sizes present. Two opposing criteria must be met: it is necessary to use sufficient material for accurate weighing and a small enough sample that the sieving operation is completed in a reasonable time.

The natural tendency is to use too large a sample, although in practice, the smaller the sample, within limits, the more reproducible the data.

As a rough guide, the amounts recommended for 8 in. diameter sieves are given in Table 5. Alternatively, the sample weight may be based on the median particle size (Table 5), but this neglects to take into account that the narrower the distribution, the smaller the sample required. A more detailed table is presented in Ref 12.

Table 5 Amount of sample required for 8 in. diameter sieves

Basis	Sample required
Particle density, g · cm⁻³	
<1.5	25
1.5-3.0	50
>3.0	100
Median diameter of particle, mm	
>2	500
2-1	200
1-0.5	100
0.5-0.25	75
0.25-0.075	50
<0.075	25

Hand sieving is time consuming but necessary for dependable dry sieving data. A representative sample is obtained and the whole of the sample is used in the analysis. The preferred method of sampling is with a spinning riffler or, failing that, a chute splitter. Coning and quartering induces segregation and should never be used with free-flowing powders.

The smallest-aperture sieve to be used should be rested on a catch pan, the tared sample placed on the mesh, and the whole sealed with a lid. The sieve should be slightly inclined to the horizontal and tapped with a cylindrical piece of wood about 20 cm long and 3 cm in diameter; this should be wrapped in duct tape to eliminate splintering. (The heel of the hand is recommended in some standards and is an acceptable alternative if the hand can take it!) The rate of tapping should be about 150 taps per minute and the sieve should be rotated $\frac{1}{8}$ of a turn every 25 taps. After about 10 min the residue is transferred to the coarsest sieve, which is nested in a second catch pan for subsequent weighing. A white card should be placed on the bench (approximately 60 cm square) so that accidental spillage may be recovered. The process is repeated in 5 min cycles until less than 0.2% of the original charge passes through the sieve. The powder is not normally removed from the sieve unless excessive blinding is occurring; both the sieve and the residue are weighed and the residual weight is determined. At the end of the sieving operation the sieve is upturned on a white sheet of paper, and the fine particles adhering to it are removed with a soft brush and added to the sieve residue.

The process is repeated with sieves of increasing fineness and the residue weights are collated. Finally, the process is repeated with the finest sieve and the fines are added to the dust collected initially. Brushing is not recommended for sieves with apertures less than 200 μm due to the possibility of damage. Sieves should be washed and dried after use. Ultrasonics should be used to remove particles clogging the apertures, or these may be leached out if possible without damage to the sieve.

The results may be expressed in terms of the nominal size, although it is preferable to use calibrated sieves. A reference set of sieves should be used after every fiftieth analysis for comparison purposes in order to detect wear. In essence, the smaller the sieve loading, the more rapid the sieving operation. The low weights, however, lead to errors in weighing and intolerable percentages losses.

It is recommended that for a dry sieving operation, the fines should be removed prior to the sieve analysis. This is effected by presieving, usually by hand, on the finest sieve to be used in the subsequent analysis. If this is not done the fines will have to pass through the whole stack of sieves, thus increasing the time of the sieving operation and increasing the risk of high powder loss. Because small particles often adhere to large ones, presieving may be carried out with water (with wetting agent if necessary) or with some other liquid in which the powder is insoluble.

The time of sieving is closely related to sieve loading, a reduction in the latter resulting in a reduction of the former. It is usual for routine analysis to machine sieve for 20 min.

If more accurate data are required it is preferable to sieve for 10 min and weigh the residues. Repeated 2 min sieving should then be carried out until the amount passing any given sieve is less than 0.2% of the initial load. Care should be taken, with brittle material, that particle breakage does not occur. Granular particles pass through the sieve more rapidly than elongated particles, although spherical particles are likely to block the apertures.

Some materials tend to form granules when sieved; this effect can often be reduced by coating the particles in order to reduce cohesiveness. Powders may, for example, be shaken in a container with 1% fatty acid (stearic acid is often used) or fumed silica. Alternatively the powder may be sieved wet. The addition of 0.1% subsieve carbon black is useful (although rather messy) for eliminating electrostatic charge.

Brittle powders are best sieved using a gentle sieving action, as is found, for example, with the Air Jet Sieve (Micron Powder Systems, Summit, NJ) or the Sonic Sifter.

For reliable data, about 5% of the sample should be retained on the coarsest sieve and a similar amount should pass through the finest. Unless the size distribution is narrow, alternate sieves (a root two progression in aperture size) are recommended.

Machine sieving is carried out by stacking the sieves in ascending order of aperture size and placing the powder on the top sieve. A closed pan, a receiver, is placed at the bottom of the stack to collect the fines and a lid is placed at the top to prevent loss of powder. A stack usually consists of five or six sieves in a root two progression of aperture size. The stack of sieves is clamped on to a test sieve shaker that is vibrated for a fixed time, and the residual weight of powder on each sieve is determined. Results are usually expressed in the form of a cumulative percentage of the nominal sieve aperture.

The three essentials required in machine sieving are an effective sieving action in order that an end point is reached, as short a time as possible to reach the end point, and reproducible results.

For routine control purposes it is usual to machine sieve for 20 min. In ASTM 452, a 20 min initial sieving period is recommended, followed by 10 min periods during which the amount passing should be less than 0.5% of the total feed. For coarse aggregates, sieving is deemed to be complete when the rate falls below 1% per min (ASTM C 136).

It is generally recommended that if losses during sieving exceed 0.5% of the total feed, the test should be discarded. Preliminary hand sieving on the finest sieve should be carried out for the removal of dust; this dust would otherwise pass through the whole nest of sieves and greatly prolong the sieving time. It would also percolate between sieves in the nest and increase powder loss.

The sieving action of some commercial machines is highly suspect, and frequently subsequent hand sieving will produce a sieving rate far greater than that produced on the machine. For the vibratory test sieve shaker, a rapid vertical movement is needed to help keep the apertures clear and prevent blinding. ASTM B 214 suggests 270 to 300 rotations per min for granular materials combined with 140 to 160 taps to reduce blinding of sieve apertures. A sieve enclosure to reduce noise levels may also be necessary.

Modifications to the methods may be necessary for materials that are not free flowing, are highly hygroscopic, are very fragile, have abnormal particle shapes, or have other properties that cause difficulty in sieving. For example, in ASTM C 92 the fines are first removed by washing through the finest sieve; the residue is then dried and analyzed in the dry state.

Manual Wet Sieving. Several methods of wet sieving using micromesh sieves have been described. An 80 kHz, 40 W ultrasonic bath can be used with the micromesh sieve resting on a support, which in turn rests on a beaker in the bath. Sieving intervals are 2 min with an initial load of 1 g. Sieving continues until no further powder can be seen passing through the sieve.

Powder (0.5 to 1 g) is dispersed in a small volume of the liquid, and the suspension is rinsed through the sieve with a suitable liquid into a glass beaker. Sieving continues by moving the sieve up and down in a glass beaker filled with the same liquid so that the direction of flow through the sieve is continuously reversed. If necessary, ultrasonics may be used. After a standardized time the operation is repeated using a second beaker containing fresh sieving liquid. Sieving is deemed to be complete when the amount passing through the sieve is visibly negligible.

For woven-wire and coarse micromesh sieves, the sieves may be mechanically rapped to facilitate sieving. The residual powder is then rinsed off the sieve and weighed, or the pretared sieve is dried and weighed. With fine micromesh sieves

an ultrasonic probe may be necessary, and the sieving liquid must have a low surface tension (e.g., acetone), or it will not pass through the sieve apertures. The procedure is then repeated with sieves of increasing fineness.

Ultrasonics are frequently used as an aid to sieving or for cleaning blocked sieves. Under these conditions, rupture of the delicate mesh readily occurs at low frequencies, about 50 Hz, and sometimes at frequencies as high as 20 kHz. Cavitation is less in hydrocarbons than in alcohol and about six times greater in water than in alcohol. Saturating the alcohol with carbon dioxide reduces the rate.

ASTM E 161-70 recommends that cleaning be carried out, 15 to 20 s at a time, with a low-power 40 kHz ultrasonic bath containing an equivolume mixture of isopropyl or ethyl alcohol and water with the sieve in a vertical position.

Wet Sieving by Machine. In most automated wet sieving methods a stack of sieves is filled with a liquid and the sample is then fed into the top sieve. Sieving is accomplished by rinsing, vibration, reciprocating action, vacuum, ultrasonics, or a combination. Commercial equipment is available in which the sample is placed in the top sieve of a stack of sieves and sprayed with water while the stack is vibrated (Fig. 19).

Fig. 19 The Retsch wet sieving machine

A wet sieving device is commercial available for the size range 10 to 100 μm that includes a sieve vibrator of variable amplitude (Fig. 20).

Fig. 20 The Alpine wet sieving device. 1, variable-amplitude vibrator; 2, support; 3, microsieve; 4, regulator with volt-meter for adjusting amplitude; and 5, timer

The Hosokawa Mikropul Micron Washsieve is one version of a wet sieving process where water is sprayed onto the surface of a vibrating sieve. The machine consists of a sprinkler section, a sieving section, and an electromagnetic section. The sprinkler rotates through the force of water to give an even spray while the sieve is vibrated to prevent blockage.

Air-Jet Sieving. The principle of operation of the Air Jet Sieve (Fig. 21) is that air is drawn upward, through a sieve, from a rotating slit so that material on the sieve is fluidized. At the same time a negative pressure is applied to the bottom of the sieve, which removes fine particles to a collecting device (a filter paper). With this technique there is less tendency to blind the apertures, and the action is very gentle, making it suitable for brittle and fragile powders. Sieving is possible with some powders down to $10\ \mu\text{m}$ in size, but with others balling occurs.

Fig. 21 Mode of action of an Air Jet Sieve

The reproducibility is much better than by hand or machine sieving. Size analyses are performed by removal of particles from the fine end of the size distribution by using single sieves consecutively.

The end point of sieving can be determined by microscopic examination of the cleanness of the sample or by adopting the same criteria as are used in conventional dry sieving. Because only one sieve is in operation at any time, a full analysis may be unduly protracted, although with sieves coarser than 30 μm the run time is less than 3 min. Sieving is more protracted with finer mesh sieves, and a sieving time of 20 min is usual with a 1 g load on a 3 in. diameter 20 μm sieve.

The Sonic Sifter. The ATM Sonic Sifter is produced as a laboratory model and as an industrial model. It is said to be able to separate particles in the 2000 to 20 μm size range for most materials and 5660 to 5 μm in some cases. It combines two motions to provide particle separation, a vertical oscillating column of air and a repetitive mechanical pulse. The Sonic Sifter moves the air in the sieve stack (Fig. 22). The oscillating air sets the sample in periodic vertical motion, which reduces sieve blinding and breaks down aggregates and yet produces very little abrasion, thus reducing sieve wear and particle breakage.

Fig. 22 Mode of action of the Sonic Sifter

The Gilson GA-6 Autosiever uses a unique double tapping action together with sonic sifting. The GA-6 features a memory for storing up to ten programs.

A downward air flow has been found to improve sieving rate for 10, 25, and 45 μm electroformed sieves using a sonic sifter operating at 107 dB and 78 Hz. The sieving rate also increased with decreasing feed rate, especially for sub-10 μm sieves.

The Seishin Robot Sifter is an automated version of the ATM in that it includes a robot arm that transports the empty sieves to a balance where they are weighed and the data are stored. At the end of this operation a nest of sieves are assembled on the balance ready to receive a sample of powder on the top sieve. The robot arm then transfers the nest of sieves to the sieving position where sieving is automatically performed. Upon completion of sieving the sieves are transferred to the balance and reweighed. The data are stored in a computer and can be printed out as required (Fig. 23).

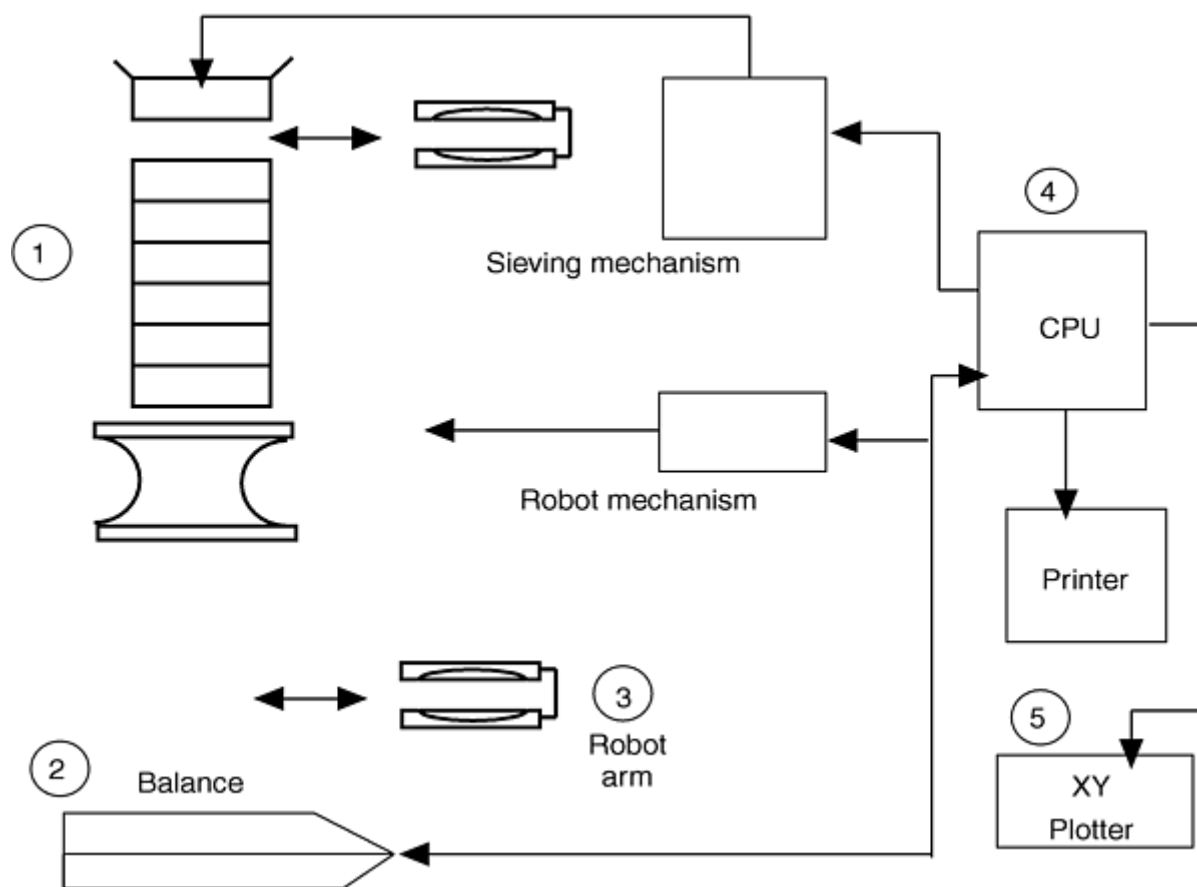

Fig. 23 The Seishin Robot Sifter

Automated Systems. Several types of sieve machines are automated for particle size analysis.

Gradex Particle Size Analyzer. Gradex uses an octagonal two-compartment drum that can be arranged with up to 14 testing sieves. The operator selects the preset cycle for the sample to be analyzed and then loads the sample into the drum, via a feed chute, onto the sieve having the smallest opening. The operator then initiates the automatic cycle, which imparts a reciprocating motion to the drum, separating the smallest fraction from the sample. At the completion of the cycle for this separation, the reciprocating motion stops and the material that passed through the sieve is weighed. The sample then passes to the next coarsest sieve and the operation is repeated. Up to six samples can be loaded into an automatic dispenser on top of the analyzer.

The cycle continues for each sieve in the cycle and the material passing through each sieve is accumulated on an electronic scale. A computer reads and stores the weight of each fraction, then tares the balance before the cycle proceeds to the next sieve. The computer uses this data to calculate and print out the size distribution. When the computer controlled cycle is selected the analysis is stopped when the throughput rate decreases to a set value. Test times vary from 5 to 15 min, depending on the analysis required.

Labcon Automatic Sieve System. The Labcon P114 computer system consists of an Epsom Pine computer mounted in a custom-made portable case containing the necessary power supplies and interface components to allow control of a sieve shaker and electronic balance. Software is included to provide a variety of methods of data handling and presentation procedures.

Gilson Compu-Sieve Analysis System includes a computer with an interface for an electronic scale or a balance for direct data collection. Any electronic balance with an RS-232 interface can be connected to the system. A record of test data is produced by a color plotter. Fifteen sieves and pans can be handled.

Ultrasonic Machine Sieving. The Retsch ultrasonic sieving apparatus was developed for accurate sieving with micromesh sieves in the 5 to 100 μm range. High-intensity ultrasonic energy (50 W) produces small bubbles that continuously collapse and reform. The resulting cavitation keeps the particles in constant motion and simultaneously prevents blocking of the mesh. Sieve loading is 100 to 500 mg unless the sub-5 μm fraction is small, in which case loading can be increased to around 2 g.

The sieves are held in a stack and sealed from each other with radial packing rings. Gravitational action carries the suspension through the stack through progressively smaller meshes.

The Vibrosonic sieve employs ultrasonic vibration of the separator mesh for industrial separation at high rates down to 400 mesh.

Sampling and Classification of Powders

Terence Allen

Appendix: Dispersion of Powders in Liquids

Ralph D. Nelson, Jr., DuPont Co., Wilmington, DE

Preparation of a dispersion is not a trivial matter. Special equipment and chemicals have been developed to facilitate the three steps of preparing a stable dispersion:

- Wetting powder clumps into the liquid
- Breaking up the wetted clumps
- Preventing flocculation of the dispersed particles

The particle size distributions (PSDs) measured for successive dispersions made from aliquots of dry powder taken from a well-mixed powder sample will be comparable only if the procedures for these three steps are optimized and carefully followed and if the chemicals used (including the liquid) are consistent. This appendix discusses the factors that affect the measured PSD in a dispersion prepared from a dry powder and indicate how they may be controlled in an optimum dispersion procedure--one for which the measured PSD is relatively insensitive to small changes in procedure.

Wetting Powder Clumps into the Liquid

The primary consequence of inadequately wetting the clumps into the liquid is that air retained in the submerged clumps may remain in the system as small submerged bubbles whose sizes are included in and bias the reported PSD. A secondary consequence is that particles may remain attached to bubbles that rise to the top and thus be carried out of the analysis region, biasing the reported PSD.

The wet-in process for a powder starts when a clump is dropped onto the liquid surface, continues as the air is displaced from the interstices (the interparticle regions or "pores" of the clump), and is completed when the clump is fully submerged with no air in the interstices. The rate at which the liquid can flow into a network of interstices is proportional to the square of the length traveled and inversely proportional to the mean interstitial diameter. Thus clumps wet fastest if they are small and are made up of large and loosely packed particles. The best way to wet a batch of powder into liquid is to sprinkle the powder as small clumps across the entire liquid surface at a rate just below that which would cause buildup of a layer of dry solids. A wetting liquid hastens the wetting by pulling itself into the interstices, thus increasing the

submersion force on the clump. If the liquid is nonwetting, the addition of a wetting agent can dramatically speed the wet-in process.

When a clump of buoyant (less dense than the liquid) particles is placed in a "Neutral" liquid that has no tendency to wet or to reject the solid (contact angle near 90°) it will submerge to a depth at which the downward force of gravity equals the upward buoyancy force of the displaced liquid. A wetting liquid will pull the clump farther into the liquid; a nonwetting liquid will push it farther out.

A clump of nonbuoyant (more dense than the liquid) particles will submerge fully in a neutral or wetting liquid, but may remain on the surface if the liquid has sufficiently nonwetting force to overcome the (submerged) weight of the particle. Because water is nonwetting for perfluoroethylene polymers (or oiled needles), they will "float" on the surface of water even though they are nonbuoyant.

How can one determine if a liquid is wetting for a particular solid? When a drop of liquid is placed on a flat, horizontal solid surface it spreads out until it attains an equilibrium shape. The contact angle is the angle from the solid surface through the liquid to the gas surface. It is related to the balance of surface tension forces at the drop perimeter where the three phases meet (the "shoreline"). A liquid is called "wetting" if the contact angle is less than 90° and "nonwetting" if it is over 90° . A liquid is most likely to be wetting for a solid that has a similar chemical structure or a similar value of interfacial energy density ("like wets like").

The surface tension (or interfacial energy density) is a measure of the force that a material exerts (in a vacuum) to pull smooth a scratch or bump on its surface. It is lowest for hydrocarbons and fluorocarbons (as low as 20 mJ/m^2), moderate for metal oxides (up to 100 mJ/m^2), and highest for metals (up to 1000 mJ/m^2) (Ref 13). *Note:* Older texts report values of surface tension in dyne/cm (equivalent to erg/cm^2); $1 \text{ mJ/m}^2 = 1 \text{ dyne/cm}$.

Breaking up Wetted Clumps

In a powder that is dry (nothing beyond a monolayer of surface moisture) or non-saturated (interparticle regions not filled with water) the individual particles are held together in clumps by forces acting at or near the points where the particles contact one another:

- Polarizability attraction
- Surface tension of the liquid located at these contacts
- Sinter bonds due to pressure on malleable materials
- Precipitation bonds from drying of solution after solid-liquid separation

The strength of bonds holding clumps together may increase with storage time due to the surface migration of material *into* the high energy contact region as a result of solubilization and mobilization due to adsorbed vapors or surface treatment chemicals or *out of* the high-pressure contact region to a low-pressure non-contact region. Some powders sold commercially have been coated with a solid or liquid to decrease the likelihood of such changes and to keep the clumps "soft" (easy to deagglomerate).

Breaking clumps to fully disperse the submerged and wetted clumps as individual particles (often called "deagglomeration") may be achieved by high shear stress or mechanical impact (Ref 14, 15, 16). This generates only a small amount of new surface area (from breaking the contact points) and thus uses only a moderate energy per unit mass of material. The surface area newly created by deagglomeration may have higher adsorptivity and reactivity than the previously existing surface of the clump. *Note:* Deagglomeration is distinct from "milling," which employs similar equipment to fragment the fundamental particles, thus generating significant new surface area and requiring a significantly higher energy per unit mass of material.

High shear stress can be achieved in high-viscosity systems (for example molten plastic or systems with very high solids loading) using:

- Slowly turning mixing paddles
- Close clearances between the shearing elements

- High rotational speed of the moving element

For intermediate-viscosity systems (for example highly loaded inks) the dispersion may be:

- Passed through the gap between two mill-rolls that are rotating with different surface velocities
- Circulated past alternately up- and down-turned teeth at the periphery of a rapidly spinning disk impeller

For low-viscosity systems (for example mineral ore in water) dispersions may be:

- Circulated through the small gaps between a slotted stator outside a close-fitting slotted rotor moving at a high RPM or
- Pumped through an annular gap around a cone rotating in a housing machined so that the clearance decreases from entry to exit
- Forced at high pressure through a very small clearance in a spring-loaded valve

At any viscosity the heat generated by the shear may be a factor limiting the extent of the operating region and thus the deagglomeration that can be achieved.

Mechanical impact can be achieved using grinding media (usually spheres or cylinders) set in motion by:

- Stirring using cross-bars or disks attached to a driveshaft
- Vibration of the container holding the liquid-powder-media mixture
- Cascading by gravity within a container rotating on a horizontal axle
- Cascading by centrifugal force within (several, for balance) rotating containers mounted on a centrifuge with their axles parallel to and offset from the axis of centrifugation

Conventional mills have a grind limit (minimum achievable particle size) about $\frac{1}{20}$ the diameter of the media, but mills with high energy input can achieve a grind limit of $\frac{1}{200}$ the size of the media. It is hard to achieve high-energy impacts in a viscous medium, so impact methods are restricted to low-viscosity systems.

Autogenous Milling. If contamination by wear fragments from the media is a problem, autogenous milling may be preferable. In this process particles are ground through impact with one another caused by:

- Directing one high-velocity jet of dispersion against another
- Vigorously stirring a highly loaded dispersion

The number of collisions is maximized if the solids loading is above 40 volume percent so that there is little liquid separating the particles.

Ultrasonic baths or probes are commonly used to prepare laboratory dispersions in low-viscosity liquids. Piezo-electric crystals attached to the container wall produce pressure waves that alternately create a vacuum (that can pull the liquid apart to form evacuated cavities) and a pressure (causing the cavities to collapse) at 10^4 - 10^7 Hz. The cavities formed next to particle surfaces are hemispheric in shape. The jets of liquid that form as these hemispheres collapse impinge on the particle surface and focus stress that can shatter the bonds holding a clump together. Because the cavitation energy is strongly attenuated as it propagates through a dispersion, cavitation occurs in only a limited volume (the "active zone") near the vibrating wall. It is important to pass all the dispersion through the active zone and to have a

sufficient total residence time there to achieve full deagglomeration without overheating the dispersion or breaking the fundamental particles. Since the presence of vapor in the cavity will decrease the intensity of collapse, the closer the liquid is to the boiling point, the less effective is ultrasonication.

Preventing Flocculation of the Dispersed Particles

Particles attract one another according to how much their interfacial energy densities differ from the intervening liquid. In an unstable dispersion, these attractive forces dominate and cause flocculation. Most size analysis techniques respond to a floc as though it were a single particle, so the particle sizes reported for a flocculated dispersion will be larger than those reported for a well-dispersed dispersion. A dispersion will be stable against flocculation if the particles repel one another or cannot approach each other closely.

Particles repel one another if they bear charges of the same sign (*electrostatic stabilization*) or are covered with molecules that prevent close approach (*steric stabilization*). The repulsion between particles may be increased by changing solution conditions or using additives called "dispersing" agents to modify particles so that they will repel one another.

Electrostatic repulsion is the simplest and generally least expensive way to stabilize a dispersion against flocculation. Surface charge can be modified by:

- pH changes that alter ionization or adsorption of surface acid and base groups
- Chemical reactions that create or deactivate ionizable surface groups
- Adsorption of ions from solution
- Ionization of an adsorbed dispersing agent
- Changing the concentration of dispersing agent to shift the adsorption equilibrium
- Using a strongly adsorbing dispersing agent to displace an unwanted adsorbate that is adsorbed less strongly

Electrostatic stabilization is most often used in aqueous systems; ionization is difficult to achieve in organic liquids.

The zeta potential characterizes the effectiveness of the charge on a particle. If the zeta potential of particles in an aqueous system (with ionic strength below 0.1 mol/L) is larger than 30 mV (positive or negative) the dispersion is generally stable against flocculation. The ionic strength is half the sum of the concentration of each ion multiplied by the square of the number of charges on that ion. It is a measure of the ability of ions in solution to form a counter-ion atmosphere about an oppositely charged particle and thus offset the effectiveness of its zeta potential.

The zeta potential for acid or base surface groups changes as a function of pH. At low pH the surface may adsorb or react with hydrogen ions to become positively charged. At high pH the surface may adsorb or react with hydroxide ions to become negatively charged. The *isoelectric pH* is the pH at which the zeta potential is zero. Isoelectric pH values range from 2 for silica to 6.4 for aluminum trihydroxide (gibbsite) to 9 for zinc oxide. Surface chemistry depends on the residual stresses at the surface, so the isoelectric point for a particle may depend upon its prior heat treatment, impurities, grinding, and aging in contact with chemicals. Since the zeta potential may drop by as much as 50 mV per pH unit near the isoelectric pH, it is important to keep the pH of a dispersion at least 1 pH unit away from the isoelectric pH to ensure stability against flocculation.

Since multiply charged ions are more strongly attracted to a charged surface than singly charged ions are, the effect of a millimole of MgSO_4 in solution is four times that of a millimole of NaCl in diminishing the effectiveness of ionic stabilization. A change from distilled to tap water or from tap water to river water can have disastrous consequences on a process if the change introduces small quantities of multiply charged ions into a slurry that is stabilized by particle charge.

Steric repulsion arises as particles covered by a steric dispersing agent approach closely. Effective steric agents contain one or more soluble ("solvated") polymeric chain segments ("loops" or "tails") and one or more strongly adsorbed anchor ("head") groups. The typical molar mass of the soluble chain segments is 5,000 to 15,000 g/mol. When two such "hairy" particles come close together, the unfavorable energetics of trying to put both sets of solvated and moving loops and tails into the same region of solvent prevent the particles from coming close enough for the attractive force to become significant. The magnitude of steric repulsion depends on polymer-liquid interactions that influence polymer chain

configurations. The hairy shell may expand or contract with temperature and liquid composition (pH, ionic strength, co-solvents). An expanded configuration generally provides the highest degree of stabilization.

Selecting a Dispersing Agent

The selection process suggested by Nelson (Ref 17) will soon be superseded by an ISO Standard 14887, "Dispersing Procedures for Powders in Liquids," currently in preparation with the author as convenor of the working group. A brief summary of the considerations involved in finding an effective dispersing agent is given below for the major chemical categories of particles.

Particles having a *natural surface charge* may be electrostatically stable to flocculation with no further treatment. If the natural charge is inadequate to prevent flocculation, these charged particles readily adsorb ionized dispersing agents that have a charge opposite that of the surface (to give a neutral particle) or multiply charged ions (which may reverse the charge on the particle).

Metal particles readily adsorb dispersing agents with highly polarizable groups and can achieve steric stabilization if coated with gelatin. Many metals react with air to form surface oxides, and many metal oxides react with water to form surface hydroxides, in which case they may be electrostatically stabilized in water if the pH is one or more units away from the isoelectric pH. Strong magnetic dipole attractions create special problems for dispersing transition metal oxide particles, which commonly have unpaired electrons that make them paramagnetic or ferromagnetic. The best approach to stabilization of magnetic particles is to provide a thick coating (for example from protein albumin) that prevents the close approach of two particles.

Highly polar materials readily adsorb dispersing agents with highly polarizable groups. A prospective dispersing agent for dispersion in aqueous systems would be sulfonated naphthalenes; for dispersion in organic systems it would be polar-substituted polyesters (acid, ester, or amine).

Nonoxide refractories consist of nonmetallic atoms held together by covalent bonds. Refractories have low values of density, polarizability, surface energy, reactivity, and adsorptivity. Because of their low polarizability, the particles are more easily dispersed in organic liquids than in water. They do not form strong flocs. A prospective dispersing agent would be a polyoxyisopropylene chain grafted to a poly-oxyethylene chain.

Polar polymers have strongly dipolar, hydrogen-bonding, or reactive groups along the chain, so their surface energies and polarizabilities are high. The particles are often incompatible with water and strongly attracted to one another, so flocculation can be a serious problem. A prospective dispersing agent would be a hydrophilic polar polymeric surfactant, which would adsorb at random points along its polymeric chain and be solvated along the rest of its chain.

Nonpolar polymers have no strongly polar groups on their repeating units. They do not require dispersing agents in nonpolar liquids. Since they have low polarizabilities, they do not form strong flocs in water, but they are not wet by water. Good dispersing agents for nonpolar polymers in water have a long nonpolar chain (that adsorbs on the polymer particles) grafted to a water-soluble chain. A prospective would be a hydrocarbon chain grafted to a polyoxyethylene chain.

Bulk and Surface Characterization of Powders

R. Iacocca, Materials Characterization P/M Lab, The Pennsylvania State University

Introduction

CHEMICAL ANALYSIS of metal powders and sintered metal components can be a complicated process, depending upon whether the analysis is to be carried out on the powder or the sintered part, and whether quantitative or qualitative information is required. These complications arise not out of difficulty in obtaining the data, but in selecting the appropriate instrument and interpreting the data correctly.

Figure 1 is a chart that can be utilized in the selection of the proper analytical tool. The first question that should be satisfied is whether powder or a sinter-bonded part is to be examined. Starting first with powder, one should determine whether the chemical information is to be quantitative or qualitative. Beyond that, one should select a technique that provides surface or bulk chemistry.

Fig. 1 Material characterization methods for particulate materials

Quantitative determination of the bulk alloy chemistry is the most sought after information for metal powder. For such measurements, atomic absorption spectroscopy (AAS) and inductively coupled plasma optical emission spectroscopy (ICP-OES) are widely employed. The former can provide the parts per billion (ppb) for some elements. AAS, however, detects one element at a time. ICP-OES has a lower resolution, typically 0.2 to 0.5 wt% for dissolved solids; however, the analysis provides quantitative data for twenty or more elements at a time, and can detect a total number of 70 elements or more (depending on the particular instrument). For both AAS and ICP-OES, the sample should be dissolved in solution.

X-ray fluorescence offers the same broad element detection of ICP-OES, however, the material can be analyzed as a bulk solid rather than dissolving the metal in an aggressive solution. For trace analyses, this method has a lower detection limit of approximately 100 ppm. This, of course, is also a function of the element to be detected.

For carbon, sulfur, nitrogen, and oxygen detection, bulk chemical analyses can be obtained using high temperature combustion and inert gas fusion, respectively. Provided great care is taken in sample preparation, resolution in the ppm range can be achieved. When considering the relative abundance of these four elements in the ambient environment, reproducibility in the ppm range is difficult to achieve.

Because of the small scale of metal powders, surface analysis should be approached with great care. Typically, microfocus electron beam techniques are the only solution for this. The scanning electron microscopy (SEM) equipped with an energy dispersive spectroscopy (EDS) system can provide a qualitative analysis of a metal particle. If the instrument can be calibrated with known standards, the analysis can be semiquantitative. Should quantification be required, the scanning electron microprobe, which is a scanning electron microscope equipped with wavelength dispersive detectors, can provide a quantitative analysis. Microprobe analysis is referred to as microchemical analysis because of the small sampling volume that is used to obtain the data. For metal powders, this small sampling volume is required to prevent the generation of spurious data.

For surface analysis of metal powder, x-ray photoelectron spectroscopy (XPS) and auger electron spectroscopy (AES) can be utilized. To interpret the data correctly, one should understand the electron beam-sample interaction. For example, when using AES, the chemical composition obtained can in no way represent the bulk chemical composition due to the tendency of certain elements to segregate.

X-ray diffraction does not supply elemental chemical analysis for metal powders. It is one of the few methods that can be used to quantitatively determine the phases that are present in a powder sample. If specific crystallographic information is needed for a particular phase that is present, transmission electron microscopy should be employed.

For a sinter-bonded part, all of the techniques described above are available, in addition to several others. Secondary ion mass spectrometry (SIMS) can be used to measure composition and trace impurity levels as a function of depth, having a detection limit in the ppb to ppm range for many elements. The sample should be flat for this method to work, thereby eliminating the analysis of powder.

By no means is Fig. 1 an exhaustive list for the characterization of particulate materials; however, the techniques listed offer a spectrum of analytical methods that are available. In the sections that follow, a more in-depth presentation is given for these techniques.

Bulk and Surface Characterization of Powders

R. Iacocca, Materials Characterization P/M Lab, The Pennsylvania State University

Microanalysis Methods

For many years, metallurgy has involved chemical analysis on a macroscopic scale with microscopic investigation of structure by means of metallography. Microanalysis is a method that combines structural (location specific) and compositional analysis in one operation. Microanalysis thus provides information concerning specimen composition on a microscopic scale; hence, microanalytical processes relate to both chemical analysis and microscopy.

Microanalysis typically involves the use of a scanning electron microscope to provide chemical analysis of micron-size areas of a surface. When used in this mode, the scanning electron microscope is termed an electron probe microanalyzer. This function is covered briefly in the section "Electron Probe X-Ray Microanalysis" in this article. A brief discussion of scanning electron microscopy (SEM) is also included. General capabilities and applications of the two methods are compared in Table 1. More detailed information on microscopic equipment and operation is contained in *ASM Handbook*, Volume 10, *Materials Characterization*.

Table 1 General capabilities and applications of SEM and electron probe microanalysis

Method	General capabilities	Applications
Scanning electron microscopy (SEM)	Imaging of surface features at 10 to 100,000 \times . Resolution of features down to 3 to 100 nm, depending on sample When equipped with a backscattered detector, microscope allows observation of grain boundaries on unetched samples, domain observation in ferromagnetic materials, evaluation of the crystallographic orientations of grains with diameters down to 2 to 10 μ m, and imaging of a second phase on unetched surfaces when the	Evaluation of crystallographic orientation of features on a metallographically prepared surface; for example, individual grains, precipitated phases, and dendrites Identification of the chemistry of features down to micron sizes on the surface of bulk samples; for example, inclusions,

	second phase has a different average atomic number	precipitate phases, and wear debris Evaluation of chemical composition gradients on the surface of bulk samples over distances approaching 1 μm
Electron probe x-ray microanalysis	Qualitative and quantitative elemental analysis of solids for elements with atomic number of 11 (sodium) or greater, detection limits of approximately 100 ppm, and at a lateral spatial resolution of approximately 1 μm Qualitative elemental analysis for light elements with atomic numbers from 5 (boron) to 10 (neon) Elemental compositional mapping of areas with dimensions as large as millimeters with spatial resolution to 1 μm	Compositional analysis of individual phases at the microstructural level in multiphase samples, for example, analysis of individual inclusions in steels and other alloys Analysis of compositional gradients at boundaries Determination of compositional homogeneity or heterogeneity at the micrometer scale in single-phase materials Compositional mapping of heterogeneous specimens to produce maps of elemental location and concentration

SEM

As a tool for examining surfaces, the scanning electron microscope provides two outstanding improvements over the optical microscope: it extends the resolution limits so that picture magnifications can be increased from 1000 to 2000 \times up to 30,000 to 60,000 \times , and it improves the depth-of-field resolution more dramatically, by a factor of approximately 300. Commercial scanning transmission electron microscopes became available around 1973, and scanning Auger microscopes, with submicron resolution, appeared in the late 1970s. These two microscopes have much in common with the scanning electron microscope, and this section compares the three types of microscopes.

A primary use of the scanning electron microscope is to produce high-resolution and depth-of-field images of sample surfaces. A second use, perhaps just as important, is to provide chemical analyses of micron-size areas.

Three types of scanning electron beam instruments are currently available: the scanning electron, scanning transmission electron, and scanning Auger microscopes. These instruments all have in common the feature of obtaining information from the surface (or volume, for the scanning transmission electron microscope) of the sample by scanning an electron beam over a raster and analyzing the various signals generated. The scanning transmission electron microscope is closely related to the conventional transmission electron microscope. The scanning Auger microscope is designed to optimize information obtained from the Auger electron signal (see the section "Auger Electron Spectroscopy" in this article). The primary detector in a scanning electron microscope produces the high-resolution images from secondary electrons. Generally, scanning transmission electron and scanning Auger microscopes use a secondary electron detector; therefore, they can also operate in the SEM mode.

Samples for SEM analysis can be any solid or liquid having a low vapor pressure (greater than $\sim 10^{-3}$ torr, or 0.13 Pa). Sample size is limited by the scanning electron microscope available. Generally, samples as large as 15 to 20 cm can be placed in the microscope, but regions on such samples that can be examined without repositioning are limited to approximately 4 to 8 cm.

Sample preparation by standard metallographic polishing and etching techniques are adequate for electrically conducting materials. Nonconducting materials are generally coated with a thin layer of carbon, gold, or gold alloy. Samples should be electrically grounded to the holder, and fine samples, such as powders, can be dispersed on an electrically conducting film, such as a silver paint that has been thoroughly dried. Samples should be free from high vapor pressure liquids, such as water, organic cleaning solutions, and remnant oil-base films.

Limitations of SEM. Image quality on relatively flat samples, such as metallographically polished and etched samples, is generally inferior to the optical microscope below 300 to 400 \times . Feature resolution, although much better than the optical microscope, is inferior to the transmission electron microscope and the scanning transmission electron microscope.

Capabilities of related techniques are summarized as follows:

- *X-ray diffraction:* Provides bulk crystallographic information
- *Optical microscopy:* Faster, less expensive, and provides superior image quality on relatively flat

samples at less than 300 to 400×

- *Scanning transmission electron microscopy, Auger electron microscopy*: Compared in Table 2.
- *Transmission electron microscopy*: Provides information from within the volume of material, such as dislocation images, small angle boundary distribution, and vacancy clusters. Superior resolution, but requires thin samples

Table 2 Comparison summary of scanning electron beam instruments equipped with secondary electron and x-ray detectors

Instrument	Features optimized	Minimum area		Comments
		Surface pictures	Microchemical analysis	
Scanning electron microscope	Surface pictures: above $\sim 500\times$ on polished and etched samples; at all magnifications on high depth-of-field surfaces; accuracy and sensitivity of microchemical analysis	4-5 nm (conventional scanning electron microscope) 2-3 nm (in-lens)	1-3 μm (EDS and/or WDS)	Can be equipped with a WDS x-ray detector that maximizes sensitivity and light-element analysis. WDS: elements with $Z > 4$, EDS: elements with $Z > 10$
Scanning transmission electron microscope	Small area microanalysis of thin films; small area diffraction	2-3 nm (SEM mode, in-lens)	5-30 nm (EDS)	Samples must be thinned; generally also functions as a transmission electron microscope; allows chemical analysis of particles characterized by transmission electron microscope observation
Scanning Auger microscope	Chemical analysis of monolayers on surfaces made by in situ fracturing, and low-Z elements on surfaces cleaned by in situ ion etching	~ 100 nm (Auger) 10 nm (SEM mode)	~ 100 nm (Auger) 1-3 μm (EDS)	Requires UHV and careful surface preparation; can also detect electron loss signal

Signals Generated by the Scanning Electron Beam. A picture of the scanned surface region can be taken using any signal generated by the electron beam. In the scanning Auger microscope, it is possible to use as many as five different signals to generate pictures. To understand the potential utility of these instruments, it is necessary to understand some elementary ideas on the nature of the signal generation when the electron beam interacts with sample surface.

When an electron beam strikes a solid surface, electrons and x-rays are emitted from the surface. The energy distribution of these signals is shown qualitatively in Fig. 2 (electromagnetic radiation of lower energies than x-rays is also emitted, which is termed cathodoluminescence). In addition to the secondary electron detector (which can also be used to detect backscattered electrons), most scanning electron microscopes are equipped with an x-ray detector, and specialized backscattered detectors are available at relatively low cost. The addition of an x-ray detector allows determination of the energy of the emitted characteristic x-ray shown in Fig. 2. Two types of x-ray detectors are used: wavelength-dispersive spectrometers and energy-dispersive spectrometers. These x-ray methods are discussed in the section "Electron Probe X-Ray Microanalysis" in this article.

Fig. 2 Energy distribution of signals generated by the electron beam

In general, the electrons generated by the electron beam can be partitioned into three types: secondary, Auger, and backscattered (Fig. 3). The intensity scale shown in Fig. 3 has been increased to reveal the details not apparent in Fig. 2. The backscattered electrons can be further partitioned into three types:

- *Type 1*: Elastically scattered
- *Type 2*: Plasmon and interband transition scattered
- *Type 3*: Inelastically scattered

Fig. 3 The energy distribution of emitted electrons at (a) low beam energy (around 1 keV) and (b) a higher beam energy (around 5 keV)

Elastically scattered electrons emerge with essentially the same energy as the beam energy; inelastically scattered electrons generally undergo many scattering interactions and emerge with a spectrum of energies lower than the beam energy. The type 2 electrons are scattered by interactions that produce a plasmon oscillation of the electrons in the sample material or a transition of sample electrons between different energy bands.

Comparison of Fig. 3(a) and 3(b) illustrates that the energies of the secondary and Auger electrons are fixed, but the backscattered electrons shift their energy values as the primary beam energy is changed.

Summary. Tables 2 and 3 provide an overview of the three types of scanning electron beam instruments and summarize the source of the signals used. Table 2 compares the scanning transmission electron microscope and scanning Auger microscope with regard to top surface analysis. The scanning transmission electron microscope enables direct probing through the sample. With the scanning Auger microscope, surface films can be probed through by ion sputtering. In general, these instruments are multifunctional.

Table 3 Comparison summary of signals used in scanning electron beam instruments

Signal type	Type	Energy	Source	Use
X-ray	Characteristic (fluorescent)	Discrete values; different for each element: Cu $K\alpha = \sim 8000$ eV; Si $K\alpha = \sim 1800$ eV	Interband transitions: $L \rightarrow K = K\alpha$, $M \rightarrow K = K\beta$; $K\alpha$: lose K electron, $L \rightarrow K$, photon ejects	Chemical analysis from micro areas in SEM, STEM, and SAM
	Continuous	Continuous	Deceleration electron	None (background noise)
Electron	Auger	Discrete values; different for each element range: 100-1500 eV; Si LMM = ~ 100 eV; Cu LMM = ~ 900 eV	Interband transitions; LMM: lose L electron, $M \rightarrow L$, M electron ejects	Monolayer surface analysis in SAM
	Backscattered (elastic)	Essentially same as beam energy	Beam electron scattered back after elastic collision	Atomic number contrast, channeling contrast, channeling patterns, and magnetic contrast in SEM
	Backscattered (inelastic)	Energies less than beam energy	Beam electron scattered back after inelastic collision	Atomic number contrast, channeling contrast, channeling patterns, and magnetic contrast in SEM
	Backscattered (plasmon and interband transition interactions)	1-1000 eV less than beam energy	Beam electron scattered back after collision producing plasmon oscillations or interband transition	Surface analysis in SAM; light-element analysis in STEM where scattering is in forward direction
	Secondary	~ 5 eV	Loosely bound electrons scattered from surface	Main signal for image formation in SEM

SEM, scanning electron microscopy; STEM, scanning transmission electron microscopy; SAM, scanning Auger microscopy

To interpret correctly the physical significance of the various signals used in the three scanning electron beam instruments, the volume below the surface from which the signal is originating must be known. In general, it is not possible to analyze quantitatively particles with diameters less than approximately 1 to 2 μm using the electron probe microanalyzer, although these particles appear to be huge on the scanning electron microscope screen. It is important to realize that the x-ray sample volume and shape vary with the electron beam voltage and the sample atomic number. Table 4 lists some estimates of the sample volume for the remaining signals. The inelastic backscattered electrons emerge from a volume roughly one-half the depth of the scattered electron range. The Auger electrons are collected from sample depths of 0.5 to 3 nm below the surface, depending on their energy. The Auger electron energies are relatively low, and only those electrons near the sample surface escape without suffering additional energy loss.

Table 4 Estimation of the volume of the various signals produced in iron by a 20 keV electron beam

Signal	Approximate volume dimensions	
	Diameter	Depth
X-ray	$\approx 1 \mu\text{m}$	$\approx 1 \mu\text{m}$
Backscattered electrons		
Inelastic (Type 3)	$\approx 0.8 \mu\text{m}$	$\approx 0.5 \mu\text{m}$
Energy loss (Type 2)	$\approx d_B$...
Elastic (Type 1)	$\approx d_B$...
Auger electrons	$\approx 1.1 d_B$	$\approx 0.5\text{-}2 \text{ nm}$
Secondary electrons	$\approx 1.2 d_B$	$\approx 10 \text{ nm}$

Electron Probe X-Ray Microanalysis

As previously noted, scanning electron microscopes are available that have been designed specifically to optimize chemical analysis with x-ray detectors. These instruments are often termed electron microprobes. Commercial electron microprobes were available before the commercial scanning electron microscope. Recent models of these machines,

which provide structural resolution nearly equivalent to the less expensive conventional scanning electron microscope, are generally superior in their function as an electron probe microanalyzer, and they include an optical system that enables viewing of the sample in situ at approximately 400×. They are, however, generally more expensive than a scanning electron microscope equipped with equivalent x-ray analyzers.

Electron probe microanalysis (EPMA) is based on the measurement of characteristic x-rays emitted from a microscopic part of a solid specimen bombarded by a beam of accelerated electrons. The electrons are focused into a beam of less than 1 μm in diameter, so that their action can be limited to the chosen microvolume at the surface of the specimen.

The ionization leading to the emission of a characteristic x-ray photon requires that the exciting electron possess or exceed a minimum energy that is also characteristic of the element and line involved. The energy required sets a minimum to the usable beam energy, which typically is between 10 and 20 keV; to keep the reactive volume within one or a few micrometers, the energy of the electron beam should not exceed 20 keV.

The x-rays generated within the specimen suffer attenuation on their way to the specimen surface. When low-energy x-rays are used in EPMA for elements of low atomic number ($Z < 15$), the corresponding signal loss and the concomitant loss of accuracy can only be limited by maintaining the beam energy toward the lower end of the range indicated above.

X-ray spectra can be obtained for all elements except hydrogen. The emission from the first ten elements consists of bands in the low-energy region, where the losses of emission by absorption in the specimen are large. Chemical effects, related to binding energies between atoms, can modify the intensity, position, and shape of these lines, thus further complicating their use for quantitative procedures. Therefore, these elements, including such important ones as oxygen, nitrogen, and carbon, are often determined by difference or stoichiometry, and the quantitative analysis for elements of low atomic number is a very specialized field (Ref 1).

Microanalysis provides information concerning specimen composition on a microscopic scale; hence, microanalytical processes relate to both chemical analysis and microscopy. Electron probe microanalysis (EPMA) produces highly element-specific signals that can be used for quantitative measurements of high accuracy. The sensitivity of the method reaches into the parts per million region for most elements; the sensitivity of EPMA is moderate only, being in most cases much poorer than that of secondary ion mass spectrometry. The key feature is the possibility of local analysis of a small region on the specimen surface. The physical separation of microscopic specimen fragments from their surroundings, which would be impracticable in most instances, is unnecessary because in EPMA the element-specific x-rays are emitted from a small region surrounding the point of impact of the electron beam, and are therefore independent of the composition of the rest of the specimen.

Two types of x-ray spectrometers are used for EPMA measurements: the energy-dispersive spectrometer or the wavelength-dispersive spectrometer. In both the energy-dispersive spectrometry (EDS) and wavelength-dispersive spectrometry (WDS) detection processes, the photoelectric effect is employed for detection. The x-ray photon is absorbed by an atom with the subsequent ejection of photoelectron, which creates charge carriers in the detection device. These charge carriers are used in different ways in the EDS and WDS detectors. Additional information can be found in the article "Electron Probe X-Ray Microanalysis" in *Materials Characterization*, Volume 10, *ASM Handbook*.

Sensitivity is 100 ppm with x-ray measurement by wavelength-dispersive spectrometry; 1000 ppm (0.1 wt%) is typical with x-ray measurement by energy-dispersive spectrometry. Poorer sensitivity occurs for light elements in a heavy matrix.

Lateral and depth spatial resolution of EPMA are approximately 1 μm , limited by electron scattering in specimen and not the focused electron beam diameter. Quantitative analysis is limited to flat, polished specimens. Unusual geometries such as fracture surfaces, individual particles, and films on substrates can be analyzed, but with greater uncertainty.

Bulk and Surface Characterization of Powders

R. Iacocca, Materials Characterization P/M Lab, The Pennsylvania State University

Surface Analysis

Elemental analysis of surfaces is performed by several techniques including Auger electron spectroscopy, x-ray photoelectron spectroscopy (also known as electron spectroscopy for chemical analysis), and ion-scattering spectroscopy. Higher sensitivities are achievable by using secondary ion mass spectrometry (SIMS). Microanalysis is also done with some SIMS instrumentation. Surface analysis has various applications in solving problems related to lubrication, catalysis, adhesion, corrosion, wear, and fracture applications in which resultant properties are determined by the composition at the surface of the solid. However, little has been reported concerning the use of such techniques in powder metallurgy.

Some specific features and characteristics of the various surface analysis techniques are summarized in Table 5. This section briefly reviews the fundamentals and provides an aid to selecting techniques for surface analysis of P/M products. More detailed information on these methods is provided in *Materials Characterization*, Volume 10, *ASM Handbook*.

Table 5 Surface analytical techniques

Testing parameters	Auger electron spectroscopy/ scanning Auger microscopy	X-ray photoelectron spectroscopy or electron spectroscopy for chemical analysis	Secondary ion mass spectroscopy	Ion-scattering spectroscopy
Principle	Emission of Auger electrons by core-hole recombination	Emission of photoelectrons by core-level excitation	Sputtering of surface atoms by ion beam	Elastic ion backscattering
Probe	~1 to 30 keV electrons	X-ray, photons	~1 to 3 keV ions	~0.5 to 3 keV ions
Signal	Derivative of electron emission energy	Electron current vs. electron binding energy	Ion current vs. mass	Ion current vs. energy
Elements detected	All except H and He	All except H	All	All except H and He
Sensitivity, general	Variable	Variable	Variable	High
Sensitivity, low atomic number	High	High	High	Low
Spatial resolution	High	Low	High	Low
Spectral shift due to chemical bonding	Yes	Yes	No	Generally no
Molecular information	Moderately effective	Yes	Usually no	Not effective
Quantitative analysis	Yes	Yes	Probably no	Yes
Beam-induced damage	Yes	No	Slight	Slight
Materials to be studied	Excellent for metals, damaging to polymers	Good for metals and polymers	Good for metals and polymers	Good for metals and polymers
Analysis, depth	<2 nm (20 Å)	~1 to 3 nm (~10 to 30 Å)	Monolayer	Monolayer
Depth-profiling analysis versus sputter	Simultaneous or sequential	Usually sequential	Usually sequential	Usually sequential

Auger Electron Spectroscopy

Auger electrons are produced whenever incident radiation--photons, electrons, ions, or neutral atoms--interacts with an atom with an energy exceeding that necessary to remove an inner-shell electron (K, L, M, . . .) from the atom. This interaction, or scattering process, leaves the atom in an excited state with a core hole, that is, a missing inner-shell electron. These excited atoms are unstable, and de-excitation occurs immediately. The energy thus released is either

emitted as a photon (x-ray fluorescence) or given to another outer shell electron, which is emitted if the energy is great enough (called the Auger transition).

In Auger electron spectroscopy (AES), the sample to be analyzed is bombarded with electrons. If an incident electron (Fig. 4a) strikes a K-shell (core-level) electron with sufficient energy to free it (Fig. 4b), the atom is left in a singly ionized state with a core-level electron vacancy. If the atom is near the surface, both the incident electron and the core-level electron are emitted from the sample as backscattered electrons, with energies below approximately 25 eV. The singly ionized atom undergoes electron rearrangement to achieve a more stable energy configuration, where an outer shell electron fills the core level vacancy (Fig. 4c).

Fig. 4 Representative electron configuration and Auger transition

These knockout events occur within a 0 to 3 nm region from the surface, which allows compositional analysis of the surface for all elements except hydrogen and helium. The probability for Auger emission exceeds that for x-ray emission as atomic number decreases. This is one of the reasons why Auger analysis has some advantages for light-element analysis. As with the characteristic x-ray emission, the energy of the Auger electrons is different for each element; therefore, analysis of Auger energies yields information on chemical identity. In addition, as with energy loss electrons, the Auger energy levels sometimes shift when an atom becomes oxidized, nitrided, and so on; therefore, information on the chemical state of the surface atoms can sometimes be obtained from Auger analysis.

The instrumentation typically used in AES includes an electron gun for primary electron excitation of the sample, an electron spectrometer for energy analysis of secondary electrons, a secondary electron detector for secondary electron imaging, a stage for sample manipulation, and an ion gun for sputter removal of atoms from the sample surface.

The electron spectrometer is usually the central component of an AES system. Various types of analyzers are in use and include sector analyzers, retarding field analyzers, hemispherical analyzers, and cylindrical mirror analyzers. For electron-excited AES, the cylindrical mirror analyzer generally offers superior signal-to-noise performance, which is associated with its high point transmission. Consequently, it remains the most prevalent spectrometer.

Detection sensitivity for most elements (except hydrogen and helium) is from 0.1 to 1.0 at%. The accuracy of quantitative analysis is limited to $\pm 30\%$ of the element present when calculated using published elemental sensitivity factors. Better quantification ($\pm 10\%$) is possible by using standards that closely resemble the sample.

Samples can be solid metal, ceramic, and organic materials with relatively low vapor pressures ($<10^{-8}$ torr at room temperature). Higher vapor pressure materials can be handled by sample cooling. Similarly, many liquid samples can be handled by sample cooling or by applying a thin film onto a conductive substrate.

Sample size can be individual powder particles as small as $1\text{ }\mu\text{m}$ in diameter. The maximum sample size depends on the specific instrument.

Interpretation of Auger spectra, particularly spectra of irregular surfaces such as powders or porous structures, is difficult due to the number of variables present, including surface contamination and roughness, dissociation effects of chemical species due to the incident electron beam itself (beam damage), and differences in sputtering rates of different chemical species. Thus, conversion of peak heights into atomic concentrations presumes an accuracy that may not exist. However, even as a qualitative or semiquantitative tool, Auger electron spectroscopy/scanning Auger microscopy has already proved invaluable in the solution of many problems.

XPS Surface Analysis

X-ray photoelectron spectroscopy (XPS) uses x-rays to remove an electron from a core level to the Fermi (1s) level. Knowing the photon energy and measuring the kinetic energy with the electron spectrometer permit direct determination of the binding energy of electrons, which is unique and can be used to identify specific elements. Because the mean free path of the electrons is very small, only electrons that originate in the top atomic layers are detected.

X-ray photoelectron spectroscopy is a surface-sensitive technique, and an inert environment such as an ultrahigh vacuum system--for example, 10^{-10} torr--is required for measurements. A typical x-ray photoelectron spectroscopy analytical chamber consists of an x-ray source, an electron energy analyzer, an electron multiplier, a pulse-counting detector, and a computer system. An ion gun is employed for sputtering and compositional depth profiling. For good resolution during profiling, the ion beam--for example, argon--must be defocused over a surface area of approximately 1 cm^2 (0.15 in.^2), because photoelectrons are collected from a surface area of several square millimeters during analysis.

Surface sensitivity of XPS is comparable to other surface analysis techniques. Data collection is slow compared with other surface analysis techniques, but analysis time can be decreased substantially when high resolution or chemical state identification is not needed. The requirement for ultrahigh vacuum conditions may necessitate an overnight vacuum pumpdown before analysis. Qualitative analysis can be performed in 5 to 10 min. Quantitative analysis requires 1 h to several hours, depending on information desired.

SIMS Analysis

In secondary ion mass spectroscopy (SIMS), an energetic beam of focused ions is directed at the sample surface in a high or ultrahigh vacuum (UHV) environment. The transfer of momentum from the impinging primary ions to the sample surface causes sputtering of surface atoms and molecules. Some of the sputtered species are ejected with positive or negative charges; these are termed secondary ions. The secondary ions are then mass analyzed using a double-focusing mass spectrometer or an energy-filtered quadrupole mass spectrometer. The principles of SIMS are represented schematically in Fig. 5.

Fig. 5 Schematic representation of the principles of SIMS

This method can be used to acquire a variety of information about the surface, near-surface, or bulk composition of the sample, depending on the instrumental parameters. If the rate of sputtering is relatively low, a complete mass spectrum can be recorded to provide a surface analysis of the outermost 5 nm of the sample. This is often termed static SIMS. Although a useful mode of operation, it is not yet a routine analytical technique. Alternatively, the intensity of one or more of the peaks in the mass spectrum can be continuously recorded at a higher sputtering rate to provide an in-depth concentration profile of the near-surface region. At very high sputtering rates, trace element or impurity analysis in the bulk is possible. Finally, a secondary ion image of the surface can be generated to provide a spatially resolved analysis of the surface, near surface, or bulk of the solid. This article will focus on the principles and applications of high sputter rate dynamic SIMS for depth profiling and bulk impurity analysis.

In general, secondary ion mass spectroscopy can provide characterization of solid samples with high spatial and in-depth resolution; due to the inherent sensitivity of mass spectroscopy, this is usually attained with high detection sensitivity as well. The extent to which these capabilities can be realized, especially in a quantitative fashion, depends on the nature of the specimen, the instrument design, and the particular instrumental parameters and methods used in the analysis. The interpretation of SIMS spectra and depth profiles can be difficult; thus, SIMS is not yet applicable for chemical analysis of unknowns in the true sense of the word. Rather, SIMS has unique capabilities for answering specific questions about specimens whose stoichiometry and matrix structure are already characterized.

P/M Applications. Secondary ion mass spectroscopy has been applied to P/M materials on a limited basis. Surface analysis of a material in powder form presents a unique problem. The surface roughness of a powder specimen generates problems with uniform sputtering for depth profiling. Roughness influences the area of sample surface that is excited and the quantity of the secondary ions that can reach the detector.

One application of secondary ion mass spectroscopy in powder metallurgy is the measurement of adsorbed or chemisorbed species on a powder surface. In this case, the technique can distinguish whether a molecular species is adsorbed intact or has dissociated at the surface. For example, secondary ion mass spectroscopy was used to determine whether carbon monoxide on the surface of nickel powder was present as molecular or dissociated carbon monoxide (Ref 2). The presence of the former leads to NiCO^+ and Ni_2CO^+ species, while the latter leads to NiC^+ and NiO^+ .

Instrumentation. There is a wide variety of instrument designs for SIMS, and the quality and applicability of the analysis depends strongly on the details of the instrumentation. Secondary ion mass spectroscopy instruments can be categorized into three broad classifications in which the distinctions refer to versatility, mass resolution, primary beam characteristics, and, in particular, imaging capability.

The simplest SIMS instrument, sometimes called an add-on, macro-, or broad-beam instrument, is intended primarily for surface analysis and qualitative depth profiling and less so for quantitative elemental analysis, microanalysis, or imaging. This is seldom a dedicated unit, but rather a set of components often used in conjunction with an Auger or x-ray photoelectron spectrometer. Figure 5 shows a simple SIMS system. The instrument uses a standard electron-impact inert ion gun that is often the same sputter gun used for sample cleaning or Auger sputter-profiling. The mass spectrometer is usually a quadrupole type, but to select a portion of the wide energy distribution of sputtered secondary ions, it requires an energy prefilter. Other than the addition of the energy prefilter, the quadrupole mass spectrometer and the ion detector are very standard.

A dedicated SIMS instrument often incorporates a more intense, finely focused primary ion beam suitable for probe imaging. Because it is unnecessary to provide the flexibility for performing analyses by AES or XPS in this type of instrument, the sample orientation and the ion collection system can also be optimized.

These instruments, often called ion microprobes, are designed primarily for quantitative in-depth profiling and microanalysis and less so for surface analysis. A typical ion microprobe uses a duoplasmatron ion source to generate inert, as well as reactive, primary ion beams. Most commercially available units use an energy-filtered quadrupole mass spectrometer, but in principle, a magnetic analyzer could also be used.

A direct-imaging SIMS instrument, usually called an ion microscope, creates a secondary beam with the ejected secondary ions. The secondary beam is mass analyzed in a double-focusing electrostatic/magnetic sector; the transmitted secondary ions can then be counted or used to create a direct image of the sample surface on a microchannel plate. Direct-imaging instruments are designed primarily for microstructural analysis and imaging, quantitative in-depth profiling, and trace element analysis. They are not suitable for true surface analysis, and due to the precise ion collection optics, the ability to treat or manipulate the specimen in situ is essentially lost.

Bulk and Surface Characterization of Powders

R. Iacocca, Materials Characterization P/M Lab, The Pennsylvania State University

Bulk Analysis

Many analytical methods are available to determine the chemical composition of powders. Most of these procedures are geared toward the analytical chemist, and a brief description of methods used in powder analysis are summarized in Table 6 and described in this section.

Table 6 Comparison of bulk analysis method for powders

Method	Samples	General uses	Limitations
XRPD^(a)	Powder samples (1 mg usually adequate) of crystalline solids	<ul style="list-style-type: none"> • Identification of crystalline phases contained in unknown samples • Quantitative determination of the weight fraction of crystalline phases in multiphase materials • Characterization of solid- 	Must be crystalline for phase identification which requires existence of standard patterns

state phase transformations			
Inert gas fusion	Solids, chips, or powders of usually 2 g or less, depending on material type and the expected amount of gases present	Quantitative determination of oxygen, nitrogen, and hydrogen in ferrous and nonferrous materials	<ul style="list-style-type: none"> • Special precautions for metals with low boiling points • Materials with stable nitrides or oxides require addition of fluxes • Method is destructive to the material
High-temperature combustion	Solids, chips, or powders of 1 g or less, depending on type of material	Determination of carbon and sulfur in metals and organics	<ul style="list-style-type: none"> • Specimen must be homogenous • Graphite-bearing specimens require special handling • Method is destructive
ICP-AES^(b)	Liquids, gases, and solids; liquids are most common; sample size of 5 to 50 mL for solutions; 10 to 500 mg for solids	<ul style="list-style-type: none"> • Simultaneous multielement analysis • Quantitative and qualitative analysis for over 70 elements with detection limits in the parts per billion (ng/mL) to parts per million (μg/mL) range • Determination of major, minor, and trace elemental components 	<ul style="list-style-type: none"> • Detection limits parts per billion to parts per million • Cannot analyze for noble gases • Halogens and some nonmetals require vacuum spectrometer and optics • Sensitivity poor for alkali elements, especially rubidium; cannot determine cesium
AAS^(c)	Solids, solutions, and gaseous (mercury) size depends on technique used--from a milligram (solids by graphite furnace atomic absorption spectrometry) to 10 mL of solution for conventional flame work	Quantitative analysis of approximately 70 elements	<ul style="list-style-type: none"> • Detection limits range from subparts per billion to parts per million • Cannot analyze directly for noble gases, halogens, sulfur, carbon, or nitrogen • Poorer sensitivity for refractory oxide or carbide-forming elements than plasma atomic emission

- spectrometry
• Basically a single-element technique

If a pressed or sintered part is to be chemically analyzed, milling, drilling, or crushing can be used to obtain a representative sample. If the part contains oil, it should be removed by using a Soxhlet extractor with a solvent as detailed in ASTM B 328. Oil can also be removed by heating in a protective atmosphere at 705 to 815 °C (1300 to 1500 °F). However, this method cannot be used for materials such as sintered aluminum because they melt.

X-Ray Powder Diffraction

X-ray powder diffraction (XRPD) techniques are used to characterize samples in the form of loose powders or aggregates of finely divided material. These techniques cover various investigations, including qualitative and quantitative phase identification and analysis, determination of crystallinity, microidentification, lattice-parameter determinations, high-temperature studies, thin film characterization, and, in some cases, crystal structure analysis. The powder method, as it is referred to, is perhaps best known for its use as a phase characterization tool partly because it can routinely differentiate between phases having the same chemical composition but different crystal structures (polymorphs). Although chemical analysis can indicate that the empirical formula for a given sample is FeTiO_3 , it cannot determine whether the sample is a mixture of two phases (FeO and one of the three polymorphic forms of TiO_2) or whether the sample is the single-phase mineral FeTiO_3 or ilmenite. The ability of XRPD to perform such identifications more simply, conveniently, and routinely than any other analytical method explains its importance in many industrial applications as well as its wide availability and prevalence.

In general, an x-ray powder diffraction characterization of a substance consists of placing a powder sample in a collimated monochromatic beam of x-radiation. The diffraction pattern is recorded on film or using detector techniques, then analyzed to provide x-ray powder data that can be used to solve such problems as those listed in Table 6.

In XRPD analysis, samples usually exist as finely divided powder (usually less than 44 μm in size) or can be reduced to powder form. The particles in a sample comprise one or more independently diffracting regions that coherently diffract the x-ray beam. These small crystalline regions are termed crystallites. Consolidated samples, such as ceramic bodies or as-received metal samples, will likely have crystallites small enough to be useful for powder diffraction analysis, although they can appear to have considerably larger particle sizes. This occurs because a given grain or particle can consist of several crystallites (independently diffracting regions). Although larger grain sizes can sometimes be used to advantage in XRPD, the size limitation is important because most applications of powder diffraction rely on x-ray signals from a statistical sample of crystallites. The angular position, θ , of the diffracted x-ray beam depends on the spacings, d , between planes of atoms in a crystalline phase and on the x-ray wavelength λ :

$$n\lambda = 2d \sin \theta$$

The intensity of the diffracted beam depends on the arrangement of the atoms on these planes.

X-ray powder diffraction techniques usually require some sample preparation. This can involve crushing the sample to fit inside a glass capillary tube, rolling it into a very thin rod shape for the Debye-Scherrer camera technique, spreading it as a thin layer on a sample holder, or packing it into a sample holder of a certain size for other XRPD techniques. In some cases, samples compatible with metallographic examination can be accommodated in powder diffractometers, but some form of sample preparation will usually be necessary. Preparation will depend on the equipment available and the nature of the examination.

A diffraction pattern can be recorded using film, analog, or digital methods. Whether film, analog, or digital data collection is used, the final data can be displayed as a graph of intensity, as a function of interplanar distance d , or as a function of diffraction angle 2θ . Many modern automated powder diffractometers can provide further data reduction, including peak finding, a tabular listing of peak intensity versus interplanar spacing, search/match software, and other computer utilities.

A powder pattern from a single-phase material will have maxima at positions dictated by the size and shape of its unit cell and will increase in complexity as the symmetry of the material decreases. For example, many metal patterns and those from simple compounds that tend to be mostly of cubic symmetry and have small unit cell edges will produce powder patterns having fewer lines or maxima than would be expected from a compound of lower symmetry or one having a very large unit cell. A pattern of a mixture of phases in which all the individual patterns are superimposed will produce a complex experimental pattern, especially when the number of phases present in the mixture exceeds approximately three or when the phases constituting the mixture are all of very low symmetry or have very large unit cell dimensions.

Phase identification using XRPD is based on the unique pattern produced by every crystalline phase. Much as a fingerprint is unique for each person, the diffraction pattern can act as an empirical fingerprint for that phase, and qualitative identification of phases can be accomplished by pattern-recognition methods that include established manual techniques and the newer methods that use computers, most of which implement programs based on heuristic algorithms. All of these methods make use of the database maintained by the JCPDS International Centre for Diffraction Data (Ref 3).

Inert gas fusion is used to determine the quantitative content of gases in ferrous and nonferrous materials. These gases, such as hydrogen, nitrogen, and oxygen, are introduced to a material by physical and chemical adsorption. Surface metals deposited on base materials physically adsorb atmospheric gases to form metal-bearing compounds. The type of metal atom available and its compatibility with the types and concentrations of atmospheric gases available under the temperatures and pressures to which the material is exposed determines the types of metallic compounds formed. Although the bond at low temperatures is unstable, the metallic compounds formed become more stable as temperature increases and the physical adsorption bond becomes a chemical adsorption bond.

As base materials are smelted, the adsorbed gases are chemically absorbed into the melt. The less stable compounds are reduced in the melt of the material, allowing each to recombine and form a more complex stable compound. The metallic elements will absorb atmospheric gases based on the affinity of the metal for each gas at various temperatures during the melt.

Processed materials are again subject to gas adsorption as the material is initially cooled and worked. Stages of drawing, rolling, heat treating, or annealing provide favorable conditions for physical and chemical adsorption of atmospheric gases. Strict control of hydrogen, nitrogen, and oxygen levels minimizes their adverse effects on material strength.

Hydrogen causes internal cracks that generally appear during cooling in such processes as drawing, rolling, or forging of the material. Materials with large cross sections can break under high or continuous stress due to internal cracks. Hydrogen is adsorbed and diffused often during working of the material. Hydrogen that is adsorbed will generally diffuse during cooling or aging. Materials used under high temperatures and pressures and exposed to high-hydrogen environments can develop structural problems due to hydrogen embrittlement.

Nitrogen in some materials can provide strength. For example, nitrogen is added to austenitic manganese steels to increase yield strength. A material can be subjected to nitriding to increase hardenability. Nitrogen may decrease ductility.

The effects of oxygen on a material are similar to those of hydrogen in that inclusions and blowholes can appear in the material. Oxygen, when combined with the carbon and nitrogen in a material, will also cause increased hardness with age. Oxygen is often the hardest to control because it is available from various sources and reactive with many metals. Smelting and processing regulate the levels of gases introduced into materials by controlling temperature, pressure, and environment, which create adsorption and absorption of gases.

Gases introduced into the material are commonly quantitatively determined using inert gas fusion. Inert gas fusion reverses the physical and chemical bonding between the gases and the metals to dissociate the gases and sweep them from the fusion area with an inert carrier gas. Resistance or induction heating of a sample in a pure graphite crucible dissociates the gas/metal bonds. Because they are formed over a wide range of temperatures, bonds can be broken only by heating the

specimen above the highest temperature at which the gas/metal bonding occurred. More information on these operations can be found in "Inert Gas Fusion" in *Materials Characterization*, Volume 10, *ASM Handbook*.

Inductively Coupled Plasma Atomic Emission Spectroscopy

Inductively coupled plasma atomic emission spectroscopy (ICP-AES) is an analytical technique for elemental determinations in the concentration range of major to trace, based on the principles of atomic spectroscopy. In theory, the technique applies to all elements except argon, and samples can be introduced as liquids, gases, or solids. In practice, favorable analytical results are obtained for approximately 70 elements, with detection limits usually attainable at the parts per billion level, and most samples are introduced in liquid form as aqueous solutions. The technique has found widespread application in the metallurgical, geological, environmental, agricultural, industrial, and biological fields and is an important technique in the modern analytical laboratory.

The ICP is an excitation source for atomic emission spectroscopy. It is an argon plasma operated at atmospheric pressure and sustained by inductive coupling to a radio frequency (RF) electromagnetic field. Argon gas flows axially through a quartz tube surrounded by three or four turns of an induction or work coil connected to an RF generator. The standard frequencies of operation are 27.12 MHz or, less commonly, 40.68 MHz, the frequencies allowed by the Federal Communications Commission for scientific and medical instrumentation. Power output is generally 1 to 5 kW.

The high-frequency current of up to 100 A flows in the water-cooled copper induction coils, generating oscillating magnetic fields whose lines of force are oriented axially inside the quartz tube and follow closed elliptical paths outside the tubes. If free electrons are present inside the tube, the induced magnetic fields cause the electrons in the gas to flow in oscillating closed annular paths inside the quartz tube space. This electron flow is termed the eddy current, and the electrons are accelerated by the time-varying magnetic field, causing collisions that result in further ionization of the argon gas and resistive heating. These electrical and magnetic fields responsible for the plasma are represented in Fig. 6.

Fig. 6 Electric and magnetic fields of the inductively coupled plasma

The energy transmission in the plasma is similar to an electrical transformer in which the induction coils are the primary winding and the ionized gas is the secondary. Because the argon gas is initially neutral and nonconducting, the plasma must be initiated by seed electrons, usually generated by a brief tesla discharge. With RF power applied, the plasma ignites instantaneously, then is self-sustaining. The resulting plasma is a highly ionized gas with temperatures in the proximity of 10,000 K.

Analytical Characteristics. The ICP as an analytical technique provides the capability of performing simultaneous multielement analysis for as many as 60 elements within 1 to 2 min. It is applicable to most elements in the periodic table and has a large linear dynamic range (calibration curves that are linear over three to six orders of concentration magnitude). This enables determination of trace, minor, and major components in a single analysis.

Detection limits are in the parts per billion (ng/mL) range for most elements; precision and accuracy on the order of 1%; and relative freedom from chemical interferences. Detection limits for the ICP are determined by first establishing a calibration curve (plot of signal intensity at a given wavelength versus concentration for a series of standard solutions). The detection limit is calculated as the concentration that would correspond to an analytical signal equal to two (or three, according to choice of definition) times the standard deviation (noise) of repeated measurements of a blank at that wavelength. This concentration is the lowest value measurable with any certainty. These detection limit values should be considered extreme limits, because they are determined under ideal situations. Practical detection limits will be somewhat higher. Some sample preparation procedures, such as dissolution and dilution, necessarily degrade the achievable detection limits of the elements in the original sample material.

Precision and Accuracy. The precision of the ICP technique is usually determined by making several consecutive measurements, then calculating the standard deviation of the replicates as a percentage of the mean value. Major causes of signal fluctuations in the ICP are small variations in the RF power applied to the plasma and changes in the nebulization process. Precision can be increased to less than 1% by close regulation of the RF power (most new instrumentation accomplishes this to $\pm 0.1\%$), by improved nebulization techniques, or by use of an internal standard. Nebulization is stabilized by using a mass flow controller to regulate the nebulizer gas flow and by use of improved nebulizer designs, such as the high-pressure crossflow nebulizer. The accuracy of the ICP technique is essentially limited by the precision and by systematic errors, such as interference effects, but is usually shown to be comparable to the precision.

Atomic Absorption Spectrometry

Atomic absorption spectrometry (AAS) is generally used for measuring relatively low concentrations of approximately 70 metallic or semimetallic elements in solution samples. The basic experimental equipment used is essentially the same as that of 30 years ago--enhanced by modern electronics, background-correction schemes, and alternate types of atomizers. The predominance of AAS in general-purpose trace-metal analysis has recently been somewhat eclipsed by modern atomic emission spectrochemical methods designed to permit solution analysis. However, its ruggedness and relatively low equipment costs keep AAS competitive. Atomic absorption spectrometry performed using the graphite-tube furnace atomizer usually remains the method of choice for ultra-trace-level analysis.

Figures 7 and 8 show the relationship between the flame atomizer versions of AAS and the related techniques of atomic fluorescence spectrometry (AFS) and atomic emission spectrometry (AES). Several features are common to all three techniques. The first is a sample-introduction/atomization system consisting of a sample sprayer (referred to as the nebulizer) and the flame. The flame desolvates, vaporizes, then atomizes (dissociates to free atoms) the fine sample droplets produced by the nebulizer. Next is the monochromator, which isolates a wavelength of light characteristic of a particular quantized transition between electronic energy levels of the outer electrons of the selected analyte element. The third component is the light intensity-to-electrical signal transducer, usually a photomultiplier tube (PMT). Finally, an electronic data-reduction system converts this electrical signal to an analytical response proportional to the concentration of analyte in the sample solution.

Fig. 7 Energy-level transitions of the atomic spectrometries. N^* , number of atoms in the excited state; N_0 , number of atoms in the ground state; I_0 , light intensity measured without the analyte present; I , light intensity measured with the analyte present. (a) Atomic emission spectrometry. (b) Atomic absorption spectrometry. (c) Atomic fluorescence spectrometry

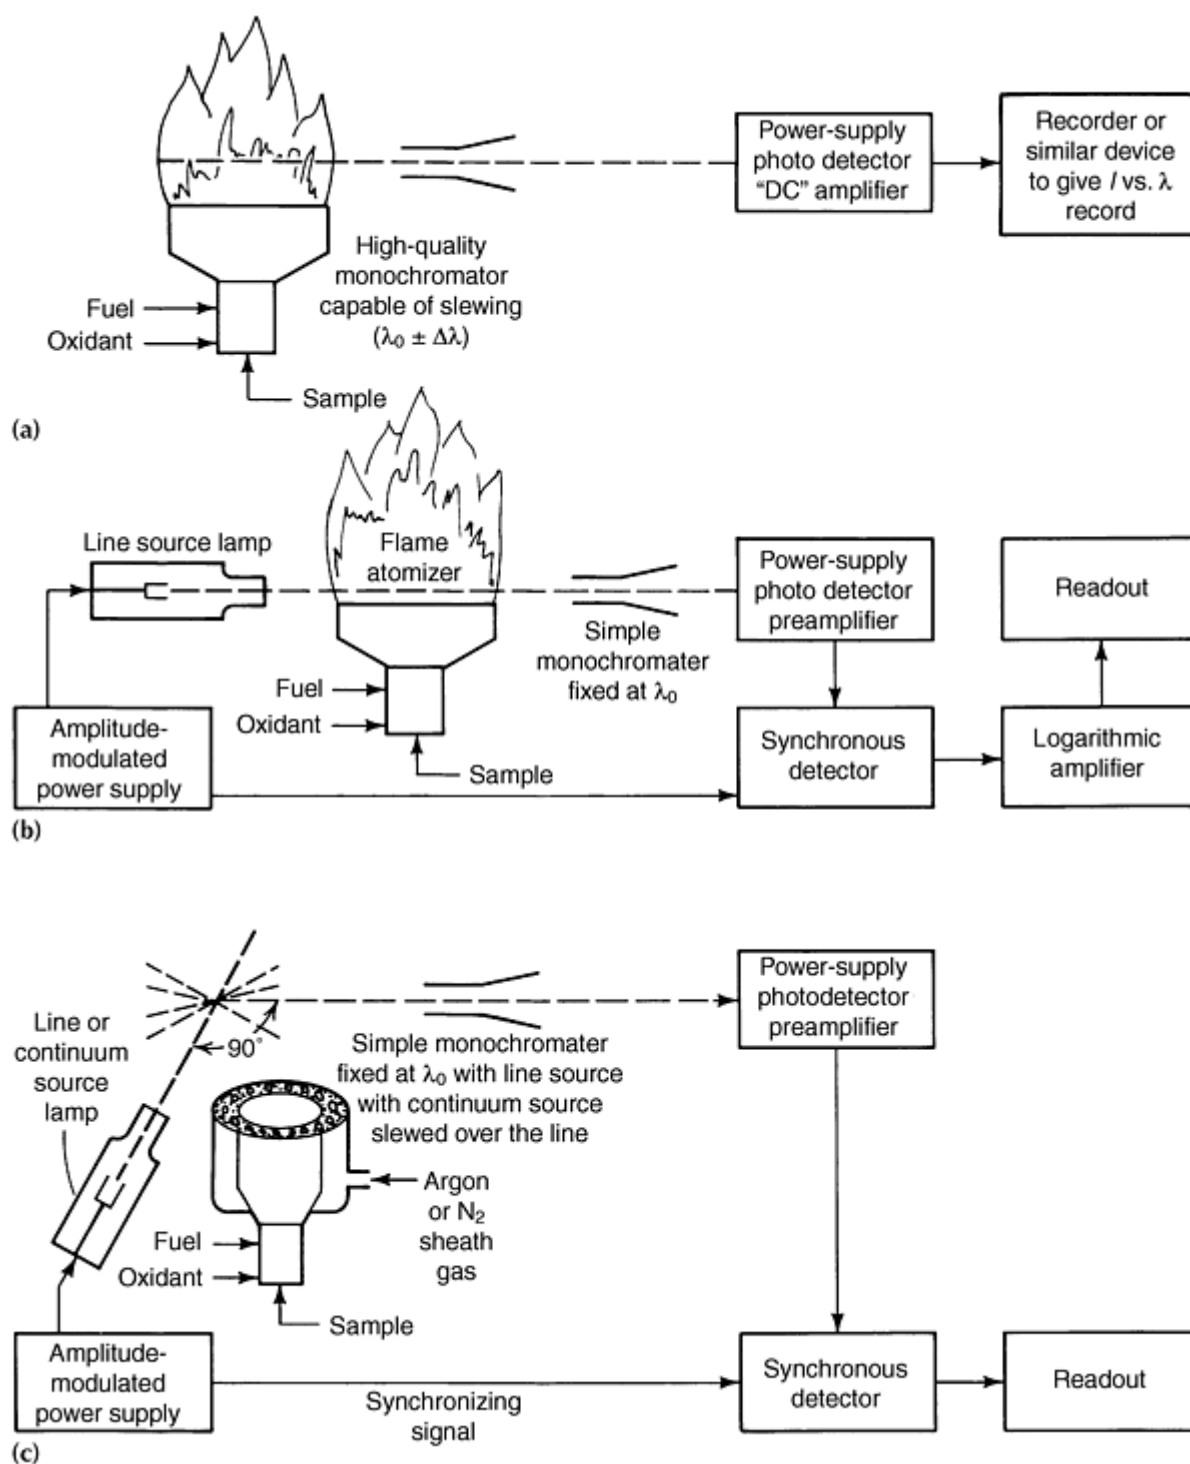

Fig. 8 Comparison of (a) flame atomic emission spectrometry, (b) flame atomic absorption spectrometry, and (c) flame atomic fluorescence spectrometry

It should be noted that within typical atmospheric pressure atomizers, the intrinsic width of the absorption/emission lines of the elements are typically from 0.002 to 0.008 nm. A comparison of these linewidths with the approximately 600 nm-wide working range of the spectrometers normally used in atomic spectroscopy indicates that approximately 10^5 resolution elements are potentially available to determine the approximately 100 elements of the periodic table. The relatively high ratio of the number of possible resolution elements to the number of chemical elements (approximately 1000:1) explains why atomic spectroscopic methods tend to be more specific than most other analysis techniques. The ease of applying this intrinsic specificity in actual practice differs substantially among the three types of atomic spectroscopy.

In atomic emission spectrometry (AES) (Fig. 7a and 8a), the flame serves an additional function not required in AAS or AFS: excitation. To produce the desired signal, hot flame gases must thermally (collisionally) excite a significant fraction of the free atoms produced by dissociation in the atomizer from the relatively populous ground-state level to one or more electronically excited states. The excited atoms emit light at discrete wavelengths corresponding to these differences in energy levels when they spontaneously relax back to the lower states. That is, the instrument "sees" the excited-state population of analyte atoms, not the ground-state population.

The ratio of the population of atoms in a thermally excited state to that in a lower energy state follows the Boltzmann distribution; that is, the logarithm of the ratio is directly proportional to the absolute temperature and inversely proportional to the difference in energy between the states. Therefore, the absolute magnitude of emission signals is temperature dependent. At typical atomizer temperatures, only a small fraction of atoms are excited to levels capable of emitting visible or ultraviolet radiation; most remain at or very near to the ground-state energy level.

Because flames do not specifically excite only the element of interest, a monochromator able to resolve close lines while maintaining a reasonable light intensity through-put should be used to reduce the probability of spectral interferences. Additional broad band-like light emitted by similarly thermally excited molecular species, for example, OH or CH flame radicals or matrix-metal oxides, complicates isolation of the desired signal from the background.

Atomic emission spectrometry usually necessitates scanning the monochromator completely over the analytical spectral line to obtain the background signal values necessary for the calculation of a correct analytical response. Reasonably inexpensive high-resolution monochromators capable of automatic correction of background emission are available.

In atomic absorption spectrometry (AAS) (Fig. 7b and 8b), radiation from a lamp emitting a discrete wavelength of light having an energy corresponding to the difference in energies between the ground state and an excited state of the analyte element is passed through the atomizer. This light is generated by a low-pressure electrical discharge lamp containing a volatile form of the analyte element. Free analyte atoms within the atomizer absorb source-lamp light at wavelengths within their absorption profiles. The absorption lines have a bandwidth approximately twice as wide as the emission profiles of the same elements in the low-pressure source lamp. In contrast to AES, ground-state (not excited state) atomic populations are observed.

The source light not absorbed in the atomizer passes through the monochromator to the light detector, and the data reduction/display system of the spectrometer outputs an absorbance response directly proportional to the concentration of analyte in the sample solution. Absorbance is the logarithm (base 10) of the ratio of the light intensities measured without (I_0) and with (I) the analyte atoms present in the light path (absorbance= $\log I_0/I$). In practice, the intensity of the source lamp is amplitude modulated at a specific frequency to permit subsequent electronic isolation of the ac light signal of the lamp from the dc light caused by the emission from species thermally excited by the atomizer. Direct current light is invariant relative to time.

Only the relatively highly populated ground-state population of the same element in the atomizer that is in the source lamp can contribute to the signal. Therefore, the analytical response of atomic absorption spectrometers is element-selective and not as sensitive to atomizer temperature variations as that of atomic emission spectrometers. In addition, the electronic lamp modulation/signal demodulation system renders the spectrometer blind to extraneous light sources. The monochromator serves only to isolate the desired analytical line from other light emitted by the one-element source lamp. Consequently, a less sophisticated monochromator suffices in AAS than is usually required for general-purpose AES. The major error signal encountered in AAS is the nonselective absorption or scattering of source-lamp radiation by undissociated molecular or particulate species within the atomizer. Several different types of background correction systems will be discussed later in this article.

Atomic fluorescence spectrometry (Fig. 7c and 8c), an emission technique, relies on an external light beam to excite analyte atoms radiatively. The absorption of light from the light source creates a higher population of excited-state atoms in the atomizer than that predicted by the Boltzmann equation at that temperature. Consequently, the absolute sizes of the atomic emission signals detected are larger than those seen in AES experiments performed with the same concentration of analyte atoms within the atomizer. A source-lamp modulation/signal demodulation scheme similar to that applied in atomic absorption spectrometers isolates the atomic fluorescence response from that emitted by thermally excited analyte, flame, or matrix species.

Atomic fluorescence spectrometry spectra tend to be much simpler than AES spectra. This is true even when bright continuum light sources, such as xenon-arc lamps, are used instead of line sources for excitation, because only those

atomic emission lines originating from energy levels whose populations are enhanced by the initial atomic absorption step can contribute to an AFS response. When line-source excitation lamps are used, this initial excitation step is very selective, and the AFS spectrum becomes extremely simple. Monochromators are often not used; the only concession to spectral isolation is the use of a photomultiplier insensitive to room light.

Atomic fluorescence spectrometry has two major sources of error. The first is chemical scavenging or de-excitation (termed quenching) of the nonequilibrium excited-state analyte atom population (that in excess of the thermally excited population) before a useful light signal can be emitted. The magnitude of this error signal depends on the concentration of the quenchers in the gas phase, which depends on the chemical makeup of the sample matrix accompanying the analyte element. Consequently, quenching introduces a potential source for matrix effects in AFS not found in AAS.

The second source of error is scatter of the exciting radiation by particulate matter within the atomizer. Some refractory metals, such as zirconium and uranium, if present in high concentrations in the sample, are apt to be incompletely dissociated or even gassified in conventional atomizers. This scatter signal is sometimes compounded with molecular fluorescence emission signals from naturally present gaseous flame species, a condition especially troublesome when continuum-type excitation sources are used.

Advantages of Atomic Absorption Spectrometry. The AAS method has been one of the most widely used trace element analysis techniques, largely because of the degree of specificity provided by the use of an analyte-line light source. This reduces the probability of "false positives" caused by matrix concomitants and serves to enhance greatly the reliability of AAS determinations performed on "unknown" samples. A background-corrected atomic absorption instrument is also one of the most reliable, albeit slow, tools available for qualitative analysis. The need for simple monochromators has maintained the cost of AAS equipment well below that of AES instrumentation having similar capabilities.

Line-excited AFS has the specificity of AAS as well as other desirable characteristics, such as a greater dynamic range and potentially better detection limits. However, obtaining appreciable improvement over AAS detection capabilities with AFS usually requires more attention to optimizing the optics, atomizer, and electronics of the system. In addition, because correction for "scatter" signals is fundamentally more important and more difficult to accomplish than is background absorption correction in AAS, no flame- or furnace atomizer-based AFS unit is commercially available.

Atomic emission spectrometry has found limited acceptance in the instrument marketplace. Although most of the better atomic absorption instruments sold during the 1960s and 1970s could be used for flame-excited AES, the instrument requirements for the two techniques are so different that the results achieved using these spectrometers did not reflect the true potential of the method. Only the recent introduction of electrical plasma emission sources, such as inductively coupled plasma (ICP) or direct current plasma (DCP), designed for the routine analyses of solution samples has prompted commercial production of fairly inexpensive and compact spectrometers optimized for AES. However, these instruments remain considerably more expensive than basic atomic absorption spectrometers.

Atomic Absorption Spectrometry Sensitivities. The periodic table shown in Fig. 9 lists typical analytical sensitivities obtained using representative atomic absorption spectrometers with either a flame or the more sensitive graphite furnace atomizer. The entries in Fig. 9 represent the magnitude of the atomic absorbance signal expected when a 1 ppm solution of the element is continuously aspirated into a flame atomizer or introduced as a discrete 25 μL aliquot into a graphite furnace.

In practice, the performance of reliable analysis requires signal magnitudes ranging from 0.01 to 1.0 absorbance unit. This is a consequence of the signal-to-noise considerations involved in measuring small differences in two relatively large light signals. This rather limited dynamic analytical range often necessitates the concentration or dilution of sample solutions before analysis.

The reasons for the extreme differences in AAS sensitivities noted in Fig. 9 can be divided into three basic categories, the first two of which affect AAS, AFS, and AES nearly equally. First, because the number of atoms within the light path at a given time fundamentally determines the instantaneous signal, the mass-based sensitivities in Fig. 9 are biased in favor of the lighter elements.

Second, a substantial number of elements do not possess ground-state lines in a region of the spectrum that is accessible with normal spectrometers and to which the gases present within normal atomizers are transparent. Less sensitive alternative analytical lines may sometimes be used, for example, with mercury and phosphorus; for other elements (most of the fixed gases), no good lines are available. Further, many elements possess a multitude of atomic energy states near the absolute ground-state level. These low-lying levels are thermally populated to some degree at the working temperature of the atomizer, which tends to reduce the fraction of analyte atoms available at any one energy level to absorb a specific wavelength of light emitted by the source lamp. This reduces the sensitivity achievable by any atomic spectroscopic technique for many of the transition, lanthanide, and actinide elements.

Lastly, none of the atomizers commonly used in atomic absorption spectrometers provides conditions capable of substantially dissociating some of the more commonly encountered forms of some chemically reactive analyte elements. For example, boron forms stable nitrides, oxides, and carbides. No practical adjustment of the operating conditions of any of the conventional atomic absorption atomizers can provide an environment that is simultaneously sufficiently free of nitrogen, oxygen, and carbon to give a favorable degree of boron dissociation. However, the combination of the much higher temperatures and inert gas environments found in electrical plasma AES sources makes boron one of the most sensitive elements determined by modern AES instruments.

Atomizers. The sensitivity of AAS determinations is determined almost wholly by the characteristics of the light source and the atomizer, not by the optics or electronics of the spectrometer. Simple, inexpensive AAS instruments have the

same sensitivity as more sophisticated models. Because the line-source lamps used in AAS have essentially the same line widths, most of the sensitivity differences noted between instruments can be attributed to differences in the atomizers.

Particle Size and Size Distribution in Metal Powders

Ronald G. Iacocca, The Pennsylvania State University

Introduction

PARTICLE SIZE AND SIZE DISTRIBUTION have a significant effect on the behavior of metal powders during processing; thus to a considerable extent, they govern the properties of the final products made from powder. Consequently, characterization of such properties is essential.

In the P/M industry, the traditional and most widely used method of particle size measurement is sieving. Sieves or screens are used not only for particle size measurement, but also for separation of powders into different sieve fractions. This twofold use of sieves, in addition to the fact that most P/M powders are -80 mesh (smaller than about 180 μm in diameter, with only minor amounts smaller than 10 μm) has been well suited to industrial applications. For powders with large percentages of -400 mesh 38 μm) particles, sieve distribution data are often complemented with other particle size measuring instruments.

Several electronic methods of particle size analysis have been developed. These generally provide higher measurement speed, resolution, and small-size sensitivity than sieves, saving time and labor while yielding more precise data. However, there has also been some confusion; particle size data for the same powder can vary greatly depending on the instrument and method used.

There are several reasons for such discrepancies. One is the phenomenon of particle shape. A definition of particle size is simple for spherical particles in which particle diameter generally is used to characterize size. Most metal powders, however, are irregularly shaped. Determination of particle size and size distribution of such powders usually is based on the measurement of certain properties, or a combination of powder particle properties--length, volume, mass, settling rate, total or projected surface area, light scattering, and electric field perturbation, for example.

From such measurements, so-called equivalent spherical particle diameters can be calculated. Equivalent spherical diameters are the diameters of spheres that have the same, or equivalent, lengths, volumes, masses, or settling rates as the irregular particles themselves.

Various methods of particle size analysis provide identical or similar analysis results for spherically shaped particles only. Typically, the various principles used to measure particle size respond differently to changes in particle shape. Very different results can be achieved for the same particle size, if particle shape deviates from spherical.

Another factor is the method of measurement. Recent advances in instrumentation and computer technology, combined with the industrial need for more accurate and reproducible data have dramatically increased the availability of commercial particle size analysis equipment over the past several years. Many different techniques, combined with dozens of commercial suppliers, have resulted in hundreds of different particle size measuring instruments and methods (Ref 1, 2, 3, and 4).

Common particle size measuring techniques include:

- Sieve analysis
- Quantitative microscopy
- Fraunhofer diffraction
- Neutron/x-ray scattering
- Time-of-flight
- Sedimentation
- Electrical zone sensing

- Mie diffraction
- Centrifugal sedimentation
- Packed bed permeability (Fisher Subsize Analyzer)
- Photon correlation spectroscopy
- Elutriation
- Field-flow fractionation
- Size exclusion chromatography

This list is not exhaustive; however, it does represent the breadth of available techniques. Several of the methods listed, such as field-flow fraction, are specific to only a few industries and would not be encountered in companies producing components from technical metal and ceramic powders. Typical methods and effective size ranges are listed in Table 1.

Table 1 Typical methods of particle size and size distribution measurement

Measuring principle	Method	Approximate useful size range, μm
Mechanical or ultrasonic agitation	Sieving	5 \sim 125 mm
Microscopy	Optical	0.5 \sim 100
	Electron	0.001 \sim 50
Electrical resistivity	Coulter counter	0.5 \sim 800
	Electrozone	0.1 \sim 2000
Sedimentation	Sedigraph	0.1 \sim 100
	Roller Air Analyzer	5 \sim 40
	Micromerograph	2 \sim 300
Light scattering	Microtrac	2 \sim 100
Light obscuration	HIAC	1 \sim 9000
Permeability	Fisher subsieve sizer	0.2 \sim 50
Surface area	Gas adsorption (BET)	0.01 \sim 20

With these different methods, it is important to understand that measurement methods are based on different analytical models (see, for example, the grouping of "measurement diameters" in Table 2 for a wide variety of methods. In reality no method measures the "true" particle size, because it is impossible to describe the size of a three-dimensional particle with a single number, therefore, all analytical methods measure an index of particle size such as geometric diameter, aerodynamic diameter, equivalent circle diameter, and so on. Because of this, even if the mathematical algorithm is accurate and the hardware is properly developed, one can obtain different "correct" particle size data on two different instruments.

Table 2 Methods of particle size analysis and nominal size ranges

Method	Nominal particle size		Measurement diameter
	μm	mil	
Sieving			
Dry	>10	>0.4	Geometrical
Wet	>2	>0.08	
Field scanning			
Optical microscopy	0.5-1000	0.02 to 40	Image
Electron microscopy	0.01-10	4×10^{-4} to 0.4	
Stream scanning			
Resistivity	0.05-500	2×10^{-3} to 20	Dynamic/Stokes
Optical	1-500	0.04 to 20	
Ultrasonic attenuation	100-1000	4 to 40	
Column hydrodynamic chromatography	0.1-1.0	4×10^{-3} to 0.04	
Sedimentation field-flow fractionation	0.01-1.0	4×10^{-4} to 0.04	

Laser Doppler velocimetry	0.01-3.0	4×10^{-4} to 0.12	
Gravity sedimentation			
Pipette	1-100	0.04 to 4	Stokes
Photoextinction	0.5-100	0.02 to 4	
X-ray absorption	0.1-130	4×10^{-3} to 52	
Centrifugal sedimentation			
Photoextinction	0.05-100	2×10^{-3} to 4	Dynamic/Stokes
Mass accumulation	0.05-25	2×10^{-3} to 1	
X-ray absorption	0.1-5	4×10^{-3} to 0.2	
Other			
Gas absorption	0.005-50	2×10^{-4} to 2	Equivalent spherical
Mercury intrusion	0.01-200	4×10^{-4} to 8	
Gas permeability	0.1-40	4×10^{-3} to 16	
Cascade impaction	0.05-30	2×10^{-3} to 12	Geometrical
Brownian motion	0.01-3	4×10^{-4} to 0.12	

Source: Ref 5

With the large number of available size measuring methods and instruments, the challenge is to select the proper instrument for a required measurement. One method does not provide more accurate results than another method but one method may indeed be more appropriate or discriminatory in a given application.

Particle Size and Size Distribution in Metal Powders

Ronald G. Iacocca, The Pennsylvania State University

Sample Preparation

A key step in the measurement of particle size distributions is the preparation of powder samples for particle size measurement. Powder dispersion is more important than the measurement methods, and instrument limitations or inaccuracies can be secondary to sample preparation.

Various sample methods include batch, continuous, or in situ measurements as outlined in Fig. 1. The procedures for the collection of representative samples and the preparation of dispersed powders or slurries are critical steps when measuring particle size distributions and estimating errors (as briefly discussed below). More detailed information of sampling and dispersion is discussed in the article "Sample and Classification of Powders" in this Volume.

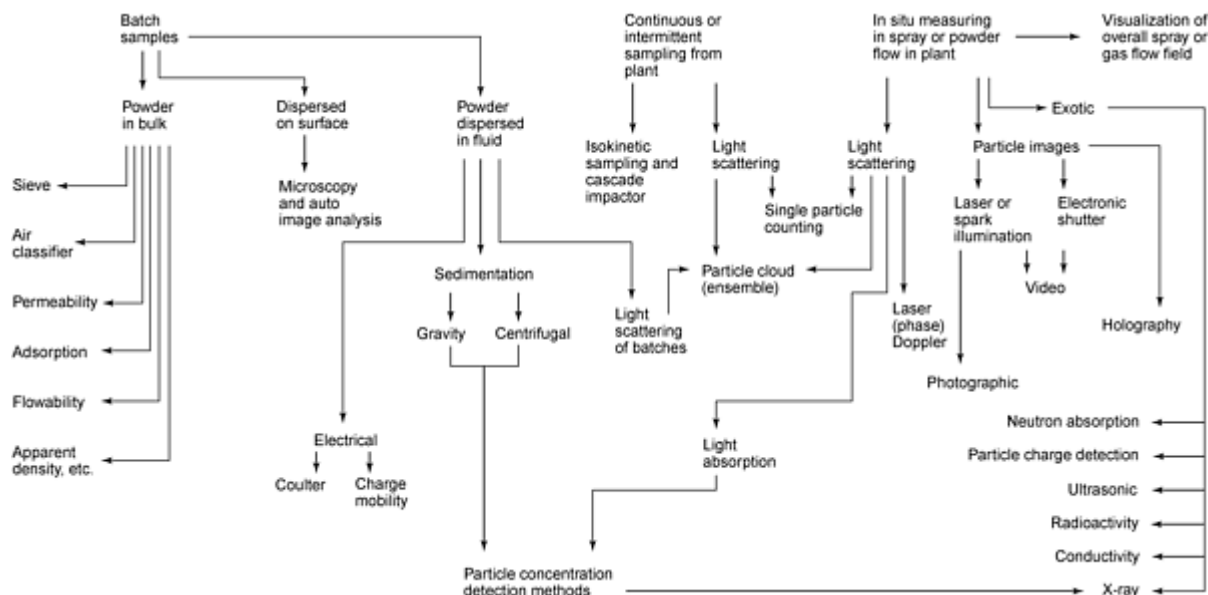

Fig. 1 General methods of powder sampling and particle size measurements

Sampling Errors. Sampling is distinguished as either a probabilistic or nonprobabilistic process where:

- *Probabilistic sampling* is when all elements of the lot are submitted, along with a probability of being selected.
- *Nonprobabilistic sampling* is deterministic rather than being based on probability, for example, as in grab sampling.

Probabilistic sampling is the preferred method.

In terms of errors, both sampling and analysis are error-generating steps, with the consequence that the overall estimation error (OE) is the sum of the total sampling error (SE) and analytical (or measurement) error (AE). Sampling and analysis involve several preparation stages, alternated with selection stages, all of which can potentially generate errors. Therefore, total overall estimation error is represented by:

$$OE = \sum_n (PE_n + SE_n) = AE_n$$

where PE_n and SE_n are preparation and selection errors, respectively, of each stage, n ($n = 1, 2, \dots$). Various errors described by Allen and Davies (Ref 6) are shown in Fig. 2. Relative particle sizes and errors depend on specific powders. For submicrometer-sized ceramic powders, dispersion-related errors appear to dominate.

Fig. 2 Dispersion error related to particle size

Dispersion. Powder dispersion includes deagglomeration and formation of a stable suspension. Of the several methods used for deagglomeration (ultrasonic probe/bath, stirring, tumbling), ultrasonication with a probe is the most effective in achieving the separation of particles held together by weak forces. An optimal level of power input to the suspension is required to achieve enhanced data reproducibility. The probe diameter, volume of suspension, power input, time of ultrasonication, and rate of power input are some of the parameters that affect deagglomeration.

The surface chemistry of the solvent-powder interface also controls the preparation of a stable suspension. A repulsive force of sufficient strength to overcome attractive forces between the particles in order to disperse them is required. The major attractive force that hinders dispersion is the van der Waals type. Electrical double-layer forces are the counterforces that can effectively provide repulsive forces. The optimal range of electrical double-layer forces in polar liquids is provided by high surface charge, moderate electrolyte concentration, and an adsorbed layer of polyelectrolyte of an appropriate type and concentration. A combination of electrical double-layer repulsion and steric stabilization has been found to be highly effective for dispersing powders in polar solvents. In nonpolar solvents, steric stabilization alone is often sufficiently effective (Ref 7) and represents the only choice available.

Particle Size and Size Distribution in Metal Powders

Ronald G. Iacocca, The Pennsylvania State University

Particle Size Measurement

Although hundreds of methods have been developed or reported for particle size measurement (Ref 1, 2, 3, and 4), there are essentially two basic methods of defining particle size. The first method is to inspect the particles and make actual measurements of their dimensions. Microscopic techniques, for example, measure many dimensional parameters from particle images. The second method utilizes the relationship between particle behavior and its size. This often implies an assumption of an equivalent spherical size, developed using suitable relationships. For example, sedimentation is used to measure size according to Stokes's law and light scattering is used to measure the size according to the Fraunhofer-Mie theories.

With the large number of available size measuring techniques, the challenge for practitioners working in this area is to select the proper instrument for the job. Table 3 and the brief summaries below introduce the most widely used characterization methods and the associated advantages and disadvantages. More detailed descriptions are in the articles that follow.

Table 3 Advantages and disadvantages of common particle-size measurement methods

Method	Particle size range	Advantages	Disadvantages
Optical particle counting	nm to mm	Extremely accurate Reproducible Direct measurement Inexpensive Can be automated	Time consuming if done manually
Sieve analysis	44 μm to mm	Widely used Relatively inexpensive Easy to use	<ul style="list-style-type: none"> • Lose accuracy over time • Particle shape can greatly skew results • Particles can adhere to screen • If done properly, process can become expensive
Permeability (Fisher Subsieve Analyzer)	0.25 to 25 μm	Widely used in certain industries Easy to use Inexpensive	Does not give a true particle size
Laser diffraction	0.01 μm to mm	Fast Reproducible Easy to use Many instruments commercially available	
Traditional sedimentation	1 to 50 μm	Widely used in certain industries Does not need to be calibrated Relatively easy to use	
Centrifugal sedimentation	10 nm to 300 μm	Ability to measure submicron particles Analysis time is greatly reduced from nongravitational methods Does not need to be calibrated Easy to use	<ul style="list-style-type: none"> • Expensive • Problems with dispersion • Must experiment to obtain optimal operating conditions
Photon correlation spectroscopy	5 nm to 5 μm	Easy to use Absolute method; does not require calibration Measures extremely small particles	<ul style="list-style-type: none"> • Complicated algorithm used to calculate particle size distribution • Agglomeration can be a real problem • Hard to verify results

Sieve Analysis. Over the years, sieving has almost become an industry standard because of its low cost and ease of operation. This method, however, has multiple disadvantages with respect to technical ceramic and metal powders. First, it is not useful in determining particle size smaller than -325 mesh (45 μm). Screens do exist with finer meshes; unfortunately, electrostatic cohesion and van der Waals forces cause the particles to adhere to the screen. Several techniques have been developed to overcome these attractive forces. By placing small rubber cubes on the sieves, a larger fraction of fine particles will pass through the mesh. Likewise, by placing the particles in an air stream (i.e., aerodynamic sieving), sieving will work more efficiently with smaller particles. Additionally, if a negative pressure is introduced underneath the sieve(s), or if the particles are sieved in a slurry, particles as small as 5 μm in diameter can be analyzed.

There are other inherent problems with sieving. Particle shape can greatly skew the distribution to the coarse or fine end. For example, if a powder has an irregular shape or ligmental shape, some of the particles will pass through the screen if they are perpendicular to the mesh, while others that do not have this orientation will not pass. Third, even if the articles have a spherical shape, the information obtained in screening is limited. For example, the designation -270 +325 for a

powder indicates that the powder has passed through a 270 mesh screen, but has not passed through a 325 mesh screen. No information is available about the actual distribution of the particles within this band.

Subsieve Analysis. The Fisher Subsieve Analyzer is an instrument that has also gained great popularity in determining average particle size, especially in the carbide and refractory metal industries. With this device, compressed air is forced through a packed bed of powder. The pressure drop across this bed is measured. Knowing the flow rate of the air and the pressure drop, it is then possible to calculate the porosity of the bed, which in turn can be converted into a surface-dependent mean particle size. This number may or may not agree with an average particle size given by a different device. One of the major flaws of this instrument is that it is assumed that the particles are monosized spheres. Furthermore, no information is provided on the particle size distribution. The instrument is effective in providing a relative ranking of powders in terms of an "effective" particle size, typically in a production environment where the powder chemistry or size shouldn't change significantly from lot to lot. In no instance should such a number be mistaken as the true mean particle size.

Quantitative Image Analysis. Optical and electron microscopy are used to directly observe and measure individual particle size and shape.

Manual particle counting is a very tedious method to obtain a particle size distribution. In years past, particles were measured from micrographs (optical or SEM). A variety of measurements were then taken from these micrographs. Such manual measurements are extremely time consuming. Despite the time intensive nature of this method, it is still widely used because of its accuracy. However, automatic counting and image analysis techniques have advanced significantly with computer technology. Recent trends in image analysis are described in the article "Particle Image Analysis" in this Volume.

Even though quantification of the images is a direct method of observing particle size, it requires the selection of an appropriate index. Mean intercept length, area equivalent diameter, Feret's diameter, maximum and minimum caliper diameter, and so forth, are all valid size measurements. With the advance of computer electronics, few people rely on manual particle counting as a primary analysis tool. Usually, it is done only to verify the accuracy of another instrument.

Laser Diffraction (Coherent Light Scattering). One of the most versatile instruments to measure particle size operates on the principle of coherent light scattering. Particles, while suspended in a slurry, are pumped in front of a laser beam. From the angle and intensity of the diffracted beam, the particle size distribution is calculated. When first developed, these instruments had an operating range of approximately 1 to 250 μm . With more sensitive detectors and more advanced technology, these light scattering devices can effectively measure particles in the range of 0.01 to more than 5000 μm . This encompasses all of the powders one would currently encounter in powder injection molding. The limits of the unit are dependent on whether the software has been programmed to include Mie scattering theory, or whether it measures Fraunhofer diffraction alone. The former permits the measurement of particles from 0.5 to 0.01 μm . At larger particle sizes, the mathematics of Mie scattering theory converge to the basic Fraunhofer theory.

Several issues must be addressed in using coherent light scattering for particle size analysis. Care must be taken to ensure that the powder is adequately dispersed in the slurry. This is accomplished by adding a surfactant to the slurry. The appropriate surfactant is a function of the powder. Table 4 shows suspension liquid/surfactant pairs that provide adequate dispersion. Note that in many instances, if the appropriate suspension liquid is chosen, a surfactant is not necessary. If the as-received powder is severely agglomerated, ultrasonic sound waves must be used in conjunction with the surfactant to break up the aggregates. If excessive ultrasonic energy is applied, the particles will fracture, producing a size distribution that is not representative of the original sample.

Table 4 Surfactant/suspension pairs for liquid powder dispersion

Powder	Surfactant	Suspension liquid
Alumina	Sodium pyrophosphate	Water
Copper	Alkylphenol/ethylene oxide condensate (Lissapol)	Water
Aluminum	Sodium, oxalate, sodium tartarate, or sodium hexametaphosphate	Water
Iron	None necessary	Rape oil and acetone; 1:1 soy bean oil and acetone
Molybdenum	None necessary	Ethanol, glycerol, acetone
Steel	Alkylphenol/ethylene oxide condensate (Lissapol)	Water

Tungsten carbide	None necessary	Ethylene glycol, oil
Tungsten	None necessary	Water, ethanol, glycerol, acetone plus rape oil

The most recent advance in coherent light scattering has been to substitute a dry powder handling system for the slurry/pump system. With the dry system, powder is delivered in front of the light source via a stream of gas. The problem of agglomeration persists even in dry-dispersing systems.

Sedimentation Methods. In certain industries, devices that characterize particle size and size distribution based on particle settling in a liquid have been widely accepted. Such industries include mineral processing, technical ceramics, carbides, and refractory metals. The basic principle behind these instruments involves the projection of a beam of electromagnetic radiation, (usually white light, monochromatic light, or x-rays) through a column containing a homogeneous suspension. Either the radiation source scans the settling column measuring the amount of light or x-rays absorbed, or the source remains at a fixed height and the flux of particles passing in front of the beam is measured. This method of particle size analysis does have advantages over other techniques in that the attenuation of the beam can be measured accurately, the sample size is small, and there is no probe inserted into the measurement that could possibly influence the measurement. As particle size decreases, however, this method becomes unreliable because of the turbulence and Brownian motion of the particles.

Stokes's Law, the principle behind sedimentation instruments, assumes nonturbulent settling of the particles. As particle size increases, turbulence increases. Therefore, there is an upper limit on the particle size that can be accurately measured with these devices. The severity of the turbulence is also affected by the density difference between the particles and the settling medium (usually water or alcohol). With most metal powder used in powder injection molding, these restrictions impose a useful upper limit of approximately 50 μm . Some equipment manufacturers have extended the lower detection limit of sedimentation instruments by introducing a centrifuge into the settling chamber; however, this also decreases the maximum particle size that the instrument can analyze.

Aerodynamic time-of-flight is a recently developed method for particle size measurement. Particles are dispersed in a stream of flowing gas, which is directed between two sensors (typically laser diodes or a split laser beam) separated by a known distance. Knowing the true density of the material (as measured by helium pycnometry or some other technique) and the time needed to traverse the fixed distance between light beams, the particle size is calculated.

Again, as with all techniques, an index of particle size is measured. Particles with aspect ratios greater than one may preferentially align in the gas stream, which may bias the data slightly. The benefit of this method is that it is an individual particle counter. Each particle that is accelerated in the gas stream is measured and recorded. Other methods such as laser diffraction produce more of an "average" particle size distribution. For spherical powders, both laser diffraction and time-of-flight report very similar data.

One of the advantages of time-of-flight is that the optical properties of the powder, that is, the relative refractive index, is not required. The material density is needed; however, that is an easier measurement to obtain.

Electrical Zone Sensing. This is one of the more established methods for measuring particle size, as well as one of the more accurate techniques. Particles are suspended in an electrolytic fluid and are pumped through an orifice in a glass tube, across which a bias is applied. As the particle passes, the resistivity of the fluid changes, which is registered as a change in potential. The change in potential is directly proportional to the cross-sectional area of the particle. No information is needed about the particles. If the particles are extremely conductive, then the instrument must be tuned to a known standard.

The major disadvantage of this method is the width of the particle size distribution that can be detected. Each orifice can accommodate a 25 \times difference in particle size. If the larger particles exceed this limit, the hole will be blocked. If the particles are too small, the voltage change that is produced will not be detected. Within the operating range of a given sample cell, the measurements are extremely accurate. Like time-of-flight, electrical zone sensing measures the size of individual particles as they pass through the opening. In this method, the size limits may be extended from 400 to 0.6 μm using a multiple tube technique. An advantage of the method is its independence from particle density, which allows powder mixtures to be sized.

Photon Correlation Spectroscopy. Instruments are available that utilize laser light scattering and digital electronics to measure particle size. This spectroscopy method is used to extract information on the dynamics of a system of

scatterers by the calculation of the correlation function of the scattered radiation. The correlation function of a scattered light signal with itself, that is, the autocorrelation function, is the Fourier transform of the power frequency spectrum of the input signal. This information is analyzed to quantify the dynamics of the scattering process that generated the signal. Some of these instruments have the capability to measure ζ potentials of the particles, by the application of laser Doppler velocimetry.

Sieve and Fisher Sub sieve Analysis of Metal Powders

Reviewed by Scott Nushart, ATM Corporation

Introduction

TWO COMMON METHODS of particle size measurement in the P/M industry are sieve analysis and the Fisher subsieve sizer. Sieve analysis is the most widely used method of determining particle size distribution of metal powders down to $\sim 5 \mu\text{m}$. The test sieve is frequently the first quality control check on the receiving dock or the last verification of product quality before shipment.

The Fisher subsieve sizer also is used extensively throughout industry, especially for process control purposes where only relative values are required. This method can measure particle sizes between ~ 0.2 to $50 \mu\text{m}$. These two common methods are briefly described in this article.

Sieve and Fisher Sub sieve Analysis of Metal Powders

Reviewed by Scott Nushart, ATM Corporation

Sieve Analysis

Standard sieves have been in industrial use for over a hundred years. Particle size distribution is controlled and certified by the powder producer and is frequently checked by the end user. Typically, a series of sieves is selected that spans the full range of particle sizes present in a powder. Sieves are stacked in order, with the largest mesh size at the top and a pan at the bottom (Fig. 1). An appropriate sample weight of metal powder is spread on the top sieve and covered. The stack of sieves is agitated in a prescribed manner (shaking, rotating, or tapping) for a specified period of time. The powder fractions remaining on each sieve and contained in the bottom pan are weighed separately and reported as percentages retained or passed by each sieve.

Fig. 1 Schematic of sieve series stacked in order of size

Sieving Equipment

Sieves. Wire cloth sieves are woven in a square mesh pattern, usually from phosphor bronze or stainless steel wires. Distributions of opening sizes and wire diameters are closely controlled to determine the nominal sieve opening.

In 1970, the American Society for Testing and Materials (ASTM), the American National Standards Institute (ANSI), and the International Standards Organization (ISO) agreed on a standard sieve series (see Table 1). Wire diameters and manufacturing tolerances are specified in ASTM standard E 11 and ISO standards 565 and 3310/1. Sieves can be purchased with the following types of certification:

- Statement by the sieve manufacturer that the wire cloth has been made in compliance with ASTM E 11
- Certification from the manufacturer listing the optical measurements at several random spots on the sieve
- Certification from the National Bureau of Standards that the individual sieve has been optically examined and meets the qualification of ASTM E 11

Table 1 Standard U.S. sieve series

Sieve designation, mesh	Sieve openings	
	μm	in.
30	600	0.0232
40	425	0.0164
50	300	0.0116
60	250	0.0097
80	180	0.0069

The National Bureau of Standards supplies calibrated glass spheres for evaluating the effective openings of testing sieves. Sieve manufacturers supply "matched sieves," where extra precision is desired for comparing the results of several locations. Frequently, a laboratory performing many sieve analyses purchases a matched pair of sieves. One sieve is used as the routine working sieve, and the other sieve is kept as a "master" to periodically check the accuracy of the working sieve.

Sieve Agitators. Several methods of advancing the powder particles through the sieve openings have been devised that rely on one or more of these mechanisms:

- Hand shaking
- Gyratory motion
- Gyratory motion with tapping
- Mechanical shaking
- Mechanical vibration
- Electromagnetic vibration
- Oscillating air column
- Vacuum

Precision and accuracy must be assessed for each test method. Microscopic checks of the end sieve fractions and reproducibility must be evaluated. The length of sieving time must be established for each method as well. Usually, the sieving period ends when the quantity passing through the sieve retaining the largest fraction of the test portion in 1 min is <0.1% of the test portion.

Standard Test Method

Testing standards have been established for the sieve analysis of metal powders. These include ASTM standard B 214, published by the American Society for Testing and Materials; MPIF standard 05, formulated by the Metal Powder Industries Federation; and ISO standard 4497, developed by the International Standards Organization. These standards are very similar and specify the following requirements:

- Standard wire cloth sieves conforming to ASTM E 11, ISO 565, or ISO 3310/1
- Mechanical sieve shakers combining a rotary motion and tapping action
- Test specimen size of ~ 100 g (3.53 oz), a nominal catch weight, for metal powders with an apparent density > 1.50 g/cm³ and a 50 g (1.76 oz) test specimen for lower apparent density powders
- Mechanical sieve shaking for 15 min or another specified time
- Weighing the powder retained on each sieve and in the bottom pan to the nearest 0.1 g (0.0035 oz) and totaling all weights
- Calculating and reporting the percentages of each sieve fraction to the nearest 0.1%

Sieving Problems

Overloaded Sieves. In this condition, the sieve surface becomes crowded with oversized and near-mesh particles after material finer than one half the size of the mesh opening has passed through. On an overloaded sieve, the weight of the oversized material tends to wedge the near-mesh particles into the openings, thus blocking passage of additional particles.

Blinded sieves (blacked sieves) result when near-mesh size particles become entrapped in the openings. When brushing fails to remove the particles, an ultrasonic wash with a wetting agent must be used to dislodge them.

Damaged sieves may be torn or have stretched and distorted mesh openings. A microscope should be used to inspect sieves regularly. Epoxy has been used to repair small defects.

Irregularly shaped particles may pass through sieve openings in a specific orientation only. For these particles to pass successfully through the openings, vibrating or shaking should be sufficient to change the orientation of all particles. Some methods of sieve agitation are more efficient than others in achieving this goal, so they must be evaluated individually.

Agglomeration of particles prevents fine particles from passing through the mesh openings. Electrostatic charges may cause fine particles to be attracted to one another, frequently forming small balls. Fine particles also can attach themselves to larger particles. The use of sieving aids, such as powdered magnesium carbonate, tricalcium phosphate, hydrophobic fumed silica, activated carbon, or commercial antistatic agents, may alleviate agglomeration. Sieving aids are usually very fine powders that pass through the sieve and collect in the pan. Thus, the amount of sieving aid used can be subtracted from the -325 mesh fraction collected.

Wet Sieving

Some difficult-to-screen materials can be handled successfully by wet sieving techniques. Apparatuses are available to handle a single sieve or a stack of sieves. Ultrasonic wet sieving devices are also available. Wet sieve analyses are cumbersome to perform and require the sieve fractions to be dried before weighing. Difficult-to-screen materials are usually very fine powders, such as silicon or aluminum, that agglomerate poorly and may not separate completely using many dry sieving techniques.

Micromesh Sieving

Micromesh sieves are produced by photoetching and electrodeposition techniques. Electrodeposition nickel produces precise square openings with planar surfaces. This thin mesh is supported by a coarser square-etched grid of nickel-plated cupronickel. These sieves are mounted in 75 or 203 mm (3 or 8 in.) stainless steel rings.

Sieve openings may be as small as 3 μm at frequent intervals. ASTM E 161 specification permits a maximum deviation of only ± 2.0 μm for sieves ranging from 125 to 5 μm .

Sieving techniques include the same mechanical shakers and vibrators used for wire cloth sieving. However, for sieves finer than 325 mesh (45 μm), most dry sieving techniques are inadequate. For these smaller size sieves, a vacuum-

type sieve can be used (Fig. 2). This type of apparatus uses suction coupled with a rotating blowback nozzle. Fine particles are suctioned through the mesh, while the blowback nozzle redistributes the powder sample on the sieve, thus breaking up agglomerates and purging the mesh openings.

Fig. 2 Micromesh vacuum sieve. (a) Apparatus. (b) Sectional view

The sieving operation is rapid and allows sieving down to 10 μm . Due to the smaller sieve diameter (75 mm, or 3 in.) and the smaller amount of open area of the finer micromesh sieves, samples of only 1 or 2 g (0.035 or 0.070 oz) are used to prevent overloading. It is also possible to perform wet sieve analyses using micromesh sieves.

Sieve Analysis Variations

Although sieve analysis is the most common method of measuring particle size by both producers and buyers, variation among results for different sieving tests of the same material is common. For example, Table 2 presents statistical results (in percentage of sample weight retained on a given sieve) for the 88 sieving tests (Ref 2). As the table shows, the values ranged widely, despite the controlled conditions of the test.

Table 2 Particle size distribution determined by dry sieving tests of 88 silica sand samples

Mesh size ^(a)	Mean particle size distribution (percentage of sample weight retained)	Standard deviation, %	Variation from the mean (percentage of sample weight retained)	
			Maximum	Minimum
30	0.08	0.051	0.20	0
40	7.03	1.281	9.80	5.10
50	36.08	1.514	40.30	33.20
70	26.38	0.417	27.20	25.50
100	19.37	0.521	20.60	18.10
140	9.28	0.396	10.00	7.90
200	1.59	0.111	1.80	1.20
270	0.12	0.044	0.30	0

(a) U.S. standard sieve series.

Table 3 also shows the number of variables for each variation source (4 batches, 88 samples, 2 sieve stacks, 2 sieving machines, and 4 operators) and the average variation (in percent) each source contributed to the total variation (Ref 2). Sampling (19.4%) and sampling reduction (33.5%) together contributed most of the total variation. The variation is largely due to the natural tendency of silica sand to segregate, which makes it difficult to take a representative sample and

then split the sample into smaller representative samples. Table 3 also shows that using two sieve stacks contributed 29.9% of the total variation.

Table 3 Number of variables and average percentage of total variation for each variation source in sieving test series

Variation source	Number of variables	Average of total variation, %
Sampling	4 batches	19.4
Sample reduction	88 samples (22 from each batch)	33.5
Sieve stack	2	29.9
Sieving machine	2	11.4
Operator	4	5.8

Source: Ref 2

Most variations in sieve analysis, both in house and between plants, can be traced to variations in sample preparation, condition of the test equipment, and testing procedure. To minimize variations in sieve analysis, it is necessary to reduce or identify the sources of variation in sampling, sample reduction, sieve stacks, sieving machines, and operators (Ref 1).

Sample Preparation. The initial conclusions drawn from sieve analysis data, which deviates from expected values, is that either the entire shipment is bad, or the test equipment is out of calibration. While either or both conclusions may be valid (if only partially), the basic tenet of securing a representative sample is often critical.

Accurate sampling is extremely difficult. At the heart of accurate sampling is the topic of segregation. If the powder is made up of individual particles of only one size (that is, no real distribution), the effects of segregation are minimal. In the real world, however, most process powders exist as distributions of particle sizes. Segregation takes place as fine particles settle down through the spaces formed between larger particles. The disparate particle sizes in a mixture cause segregation.

To counteract segregation effects, representative samples should be obtained from a moving stream of powder. The entire stream of powder also should be taken for many short increments of time in preference to part of the stream being taken for the entire time (Ref 3). Sampling methods that do not follow these rules are second-best methods likely to cause errors. Alternative sampling methods--such as scoop sampling, coning and quartering, and riffing--are not precluded, just noted to be less than ideal. More information on the critical aspect of sampling is discussed in detail in the article "Sampling and Classification of Powders" by Terence Allen in this Volume.

Great care also must be taken to ensure uniform sampling. Not only is it important to sample correctly, but similar methods are needed to ensure similar results. For example, when the entire sample must be reduced or split, using one person and method to reduce each sample minimizes variation. Proper gross sample reduction should be performed as directed in the *ASTM Manual on Test Sieving Methods* and other industry-specific publications.

Condition of the Test Equipment. Understanding the process of a test sieve helps demonstrate the importance of keeping the equipment in top condition. Regardless of whether the sieve and contents are hand or mechanically agitated, the powder is constantly being reoriented in relation to the sieve openings. Those particles that are considerably smaller than the openings will clear first, followed by particles closer to the size of the openings. Eventually, the end point is approached--that point at which a negligible percentage of particles continues to pass through the openings.

Unfortunately, this description assumes that the test sieve and the powder being sieved are both perfect; the test sieve is assumed to have perfectly uniform square openings of the same size, while the powder is assumed to have regular, blocky, or spherical particles with a perfectly even distribution. These assumptions, of course, are inaccurate. The unique characteristics of individual powder samples and individual testing sieves combine to create another variable.

Standards and Specifications. Because test sieves are fabricated from a woven mesh material, variations in the weave are common. The chances of locating two sieves of identical distribution are extremely remote. This adversely affects the reproducibility of test results between sieves. To reduce testing variations, the dimensional integrity of the sieve openings must be closely controlled. The stringent standards imposed by ASTM, the International Standards

Organization (ISO), and other regulatory bodies have created tolerance factors that allow for variations in the weave while striving to maintain a level of uniformity in test grade sieve cloth.

Each sieve should comply, as a minimum requirement, with the ASTM E 11 specification on "Wirecloth Sieves for Testing Purposes." This specification addresses the topics of nominal opening size, permissible variations in the opening size and wire diameter, general sieve frame construction parameters, and calibration procedures. In addition, appendices to the specification provide guidelines on how these dimensional values should be checked.

By compliance with standards, both powder suppliers and users have a common starting point, a basis of comparison. To further reduce performance variations, sieves characterized or physically measured as being near the nominal opening size or centerline of the tolerance should be specified.

Care and Maintenance. Test sieves, like any other piece of analytical laboratory equipment, require regular care to maintain their performance standards. The sieves should be kept clean and dry at all times and be stored in the cardboard carton provided or a suitable cabinet.

For the test sieve to perform properly, the wire cloth must be taut and free from variations in opening size. Regular cleaning, preferably in a low-power ultrasonic cleaner filled with a room temperature solution of mild detergent and water, will prevent the buildup of particles trapped in the mesh and prolong the useful life of the sieve. Cleaning should be done regularly to ensure good results.

Any brushing done on the woven wirecloth increases the risk of wirecloth variations, especially in mesh sizes finer than 80, where the fine wires are more likely to bend, distort, or even break. Practicality necessitates brushing in most instances, but utmost care should be exercised.

Agitation methods. The method for shaking or agitating the sieve must also be carefully monitored to reduce interlab variations. Hand sieving generally exhibits the greatest incidence of variations between operators. The amount of shaking and tapping force imparted to a sieve stack by an assortment of operators is difficult to quantify.

For this reason, many labs have introduced mechanical sieving devices (sieve shakers) into their regular programs to help minimize variations between operators. Unfortunately, machines from different manufacturers can provide clearly divergent data after a similar amount of agitation time. Variations can also be seen in test runs on similar machines from the same manufacturer. Standardization tests should be undertaken to reduce variations and to ensure reproducibility within each lab and correlation between labs.

Data formats for sieve calibration are also important. For example, if a sample is run through two different sieves, it is desirable to compare the sieves by both percentage of sample weight and cumulative percentage of sample weight retained (Ref 2), as shown in Table 4. The percentage of sample weight passing a given sieve more accurately shows whether each sieve meets the standards than does the cumulative percentage of sample weight retained, which is influenced by the sieve above it. Though a tight or loose sieve can pass either fewer or more particles to the next sieve, very few near-size particles are likely to pass to the next sieve. Thus, presenting calibration results in both percentage of sample weight passing and cumulative percentage of sample weight retained will help eliminate the effect of the preceding sieve on the sieve in question (Ref 2).

Table 4 Sieve calibration results for two sieve stacks (in percentage of sample weight passing and cumulative percentage of sample weight retained)

Mesh size ^(a)	Sample weight passing, %		Cumulative sample weight retained, %	
	Sieve stack 1	Sieve stack 2	Sieve stack 1	Sieve stack 2
20	99.5	99.6	0.5	0.4
30	76.3	83.5	23.7	16.5
40	58.7	58.8	41.3	41.2
50	32.2	32.6	67.8	67.4
70	13.8	14.1	86.2	85.9
100	6.3	6.4	93.7	93.6
140	2.3	2.6	97.7	97.4

200	0.0	0.1	100.0	99.9
Pan	0.0	0.0	100.0	100.0

Source: Ref 2

(a) U.S. standard sieve series.

Test Procedure. How a test procedure is performed can provide valuable insight into why variations occur. Specific documentation and adherence to a given procedure ensure good interlab correlation. The importance of proper documentation of test procedure is highlighted by the following example.

Example. When the analysis numbers did not match between a referee lab and a powder supplier, the referee lab asked about the specific test methods. The vendor said the sample was washed through a 400 mesh sieve using a fifty-fifty mixture of acetone and deionized water. The residue was then oven dried for 60 min at 300 °F, run through a demagnetizing coil, and put through the rest of the sieves. When the customer and the referee lab tried the procedure, they found complete correlation.

Summary. Good laboratory procedure is essential. Particle size analysis with a stack of testing sieves is an analytical procedure like any other used to determine the physical or chemical properties of a substance. The level of care taken during all phases of an analysis is directly proportional to the success ratio of the testing.

Communication between vendor and buyer can eliminate a great deal of misunderstanding and expense. If both parties have a full understanding of what is expected, questions regarding sampling, equipment, and procedures will be satisfactorily answered before any particles are analyzed.

Common sense is important. If the sampling techniques, particle size measuring techniques, and accepted testing procedures are reasonable to both parties, there will be no surprises. No phase should be expected to provide a higher level of test accuracy than any other phase. If the sampling phase is highly accurate, the equipment and procedural phases of the test should parallel that level of accuracy.

Sieve and Fisher Sub sieve Analysis of Metal Powders

Reviewed by Scott Nushart, ATM Corporation

Fisher Sub sieve Sizer

The Fisher subsieve sizer is another common industrial method that allows particle size measurements in the range of 0.2 to 50 μm . It is a simple method to measure particle sizes below the range of sieve analysis.

The Fisher subsieve sizer is a simple, inexpensive permeameter, which measures the flow of air through a packed powder bed. From this measurement, average particle size and porosity can be calculated from a chart that is an integral part of the instrument. The Fisher subsieve sizer is used extensively throughout industry, especially for process control purposes where only relative values are required.

Frequently, however, the results are often misinterpreted to designate an exact particle size. Consequently, analysis results refer to a Fisher "number" rather than a size. Fisher subsieve numbers should not be compared with size results from other measuring techniques, as frequently no correlation exists. Figure 3 illustrates a typical Fisher subsieve sizer, and Fig. 4 provides a schematic of the method.

Fig. 3 Fisher subsieve sizer

Fig. 4 Schematic of Fisher subsieve sizer

Permeameters accurately and precisely measure permeability. They do not measure surface area or particle size. The flow through a porous compact depends on the structure of the pores. Flow, therefore, depends on the porosity, particle shape, particle size, particle size distribution, and method of compaction, all of which affect pore structure. Conversion of the measured permeability to a surface area is accomplished by the Kozeny-Carman equation:

$$K = E^3 / (1.0 - E^2) B S_w^2 \rho^2 \quad (\text{Eq 1})$$

and

$$E = (V_{\text{bed}} - V_{\text{powder}}) / V_{\text{bed}}$$

where K is permeability of the powder bed; E is porosity of the powder bed; V is volume, cm^3 ; ρ is true, or absolute, density of the powder material, g/cm^3 ; S_w is surface area per unit weight of powder, cm^2/g ; and B is constant.

From Eq 1, it can be seen that permeability is related to three macroscopic quantities: bed porosity, surface area, and particle density. Average particle diameter (d_m), also known as the Sauter mean diameter, the surface mean diameter, or the volume surface mean particle size, is calculated from the surface area by:

$$d_m = 6/\rho S_w$$

For powders of the same composition and of similar size distributions, Eq 1 is probably satisfactory. However, if particles can be packed differently and exhibit the same porosity, but with different pore structures, this relationship may not hold. For instance, two powders of the same chemical composition with different particle size distributions have been given the same Fisher subsieve numbers. Comparison of results from the Fisher subsieve sizer with those from other surface area and size distribution techniques may show no agreement and should not be undertaken.

When particle shape, size, and distribution are essentially the same and do not vary significantly from one production lot to another, Fisher subsieve analysis provides adequate comparisons for quality control purposes. The major limitations include constant sample packing and instrument calibration.

Operation. ASTM B 300 standard, "Average Particle Size of Powders of Refractory Metals and Compounds by the Fisher Subsieve Sizer," provides calibration and operating instructions for Fisher subsieve analysis. Standard ASTM C 721, "Average Particle Size of Alumina and Silica Powders by Air Permeability," also provides guidelines. These specifications are based on the Fisher subsieve sizer instruction manual (Ref 4).

The output of an air pump is regulated to a pressure head of 50 cm (19.7 in.) of water by the water level in the standpipe. At this constant pressure, the flow through the packed powder bed is measured by the water manometer. Calibration is accomplished by varying the leakage rate through the calibrating valves.

The powder sample is weighed to 0.1 g (0.003 oz) and placed in the sample tube. Using a rack and pinion, it is compacted with a 222 N (50 lb) force applied with a torque wrench. This technique minimizes sample-to-sample packing variation. Porosity is determined from the compacted sample height and the instrument calculator chart.

The sample tube is then placed in the air system, and after equilibrium is reached, the manometer water height is measured. The instrument calculator chart is used to obtain the average size. If the sample height is such (high or low) that the calculator chart cannot be used, the actual height (in centimeters) above the base line is measured for both sample height and manometer water height. These values are used in the following equation to provide calculated values. The calculator chart uses a modification of Eq 1:

$$\text{Porosity} = [LA - (M/\rho)]/LA$$

and

Fisher number

$$= CL(M/\rho) \sqrt{2H/(P - 2H)[AL - (M/\rho)]^3}$$

where L is sample height after compaction, cm; A is cross-sectional area of sample tube, cm^3 (1.267); M is weight of sample, g; ρ is true, or absolute, density of powder material, g/cm^3 , H is height of water column above the base line, cm; P is overall air pressure, cm (50 cm, or 19.7 in., of water); and C is instrument constant (3.80).

If the sample weight is made equal to the true density, the equation is simplified:

$$\text{Porosity} = (LA - 1.0)/LA$$

and

$$\text{Fisher number} = CL\sqrt{2H/(P - 2H)(AL - 1.0)^3}$$

Standardization. The Fisher subsieve sizer must be standardized daily (or more frequently, if necessary) according to the procedures given in the instrument manual (Ref 4). Monitoring of the sample post height, which sets the chart base line as the instrument zero, is frequently overlooked. This can be verified easily by placing two filter paper sheets between the two sample tube porous plugs located on top of the sample post. The rack is brought down in contact with the upper porous plug, and the pointer is checked to see that it is on the base line. If it is not, post height is adjusted until the measurements coincide. This is an infrequent but critical adjustment.

A method of standardization uses a Fisher ruby orifice mounted in a sample tube, which is calibrated by the manufacturer against the primary standard, the National Bureau of Standards Cement No. 114. Operating the Fisher subsieve sizer with the calibrating tube in place and the chart positioned to the proper porosity produces a water column of a predetermined height. This indicates a size on the chart that is equal to that engraved on the side of the tube. If it does not, the internal calibration valves are adjusted until the correct value is obtained. Other secondary standards may be used and include any uniform powder that has an accepted Fisher subsieve number.

Results. Because analysis results are obtained by interpolation of the pointer position between lines on the calculator chart, they should be reported with varying intervals and places after the decimal point, as indicated in ASTM C 721, Section 9.1. Reading and chart line intervals for given particle ranges are shown in the following:

Particle range, μm	Chart line interval, μm	Reading interval, μm
0.2-4	0.1	$\pm 0.2^{(a)}$
4-8	0.2	± 0.1
8-15	0.5	$\pm 0.1^{(b)}$
15-20	1.0	± 0.2
20-25	5.0	± 1.0

- (a) For porosities less than 0.55, the reading interval for the 0.5-4 μm range is $\pm 0.5 \mu\text{m}$.
- (b) For porosities greater than 0.6, the reading interval for the 11-15 μm range is $\pm 0.2 \mu\text{m}$.

In one laboratory, a five-year weekly evaluation of the ASTM B 459 tungsten powder gave an average of 1.23 μm and a standard deviation of 0.012 μm . Fisher subsieve numbers are generally agreed to be precise within $\pm 5\%$. Because of the care taken in making the measurements, many laboratories report $\pm 3\%$ precision.

Sedimentation Methods for Classifying Metal Powders

Introduction

SEDIMENTATION is a mechanism for classifying metal powders according to their settling rate in a fluid. This measurement is based on Stokes's law of fluid dynamics, which states that, at low velocities, the frictional force on a spherical body moving through a fluid at constant velocity is proportional to the product of the velocity, the fluid viscosity, and the radius of the sphere.

The Stokes equation is a relationship between settling velocity, U_{st} , and particle diameter, D :

$$U_{st} = \frac{(\rho_s - \rho_f) g D^2}{18\eta}$$

where ρ_s is solid density, ρ_f is fluid density of viscosity η , and g is gravitational acceleration (Ref 1). The particle size distribution can be determined by examining a sedimenting suspension of the powder. Changes with time in the concentration of density of the suspension at known depths are determined, and the size distribution is determined from these data (Ref 2).

Sedimentation is routinely used to determine particle size and size distribution. Among the number of sedimentation methods available, only a few are commonly used for metal powders--the micromerograph and light and x-ray turbidimetry. Another analyzer using the sedimentation method is the roller air analyzer; however, it is no longer manufactured, and its standards are being withdrawn.

To obtain valid results, convection currents must be avoided in the suspending fluid, and the relative rate of motion between the fluid and the powder particles must be slow enough to ensure laminar flow. This generally restricts the particle sizes that can be determined to the subsieve range.

Particles should be large compared with inhomogeneities in the fluid, which for sedimentation in air restricts the available methods to particles $>5 \mu\text{m}$. For sedimentation in liquids, particle sizes down to $0.1 \mu\text{m}$ can be determined.

Particles in the suspension must be perfectly dispersed, and the suspension must be diluted enough to guarantee independent motion, which translates to a maximum concentration of ~ 1 vol% of particles in the suspending medium.

Finally, wall effects should be minimized; consequently, the inside diameter of the sedimentation chamber should be sufficiently large to overcome this phenomenon.

Sedimentation Methods for Classifying Metal Powders

Micromerographs

This equipment is a sedimentation balance occasionally used for determining the particle size distribution of subsieve metal powders. The powder is suspended in air by projecting the sample with a burst of nitrogen through a deagglomerating device consisting of a conical annulus into the settling chamber.

The chamber consists of a thermally insulated vertical aluminum tube with a 10 cm (3.94 in.) inside diameter that is 2.5 m (8.20 ft) high. The pan of an automatic balance that weighs the amount of powder settling on it is located at the bottom of the chamber. A recorder calculates the cumulative weight of powder settled as a function of time. Particle size distribution is calculated from this value on the basis of Stokes's law. Particle size distribution ranging from 2 to 100 μm can be determined with this instrument. One limitation of the method is the tendency of powder particles of various sizes to cling to the wall of the column.

Sedimentation Methods for Classifying Metal Powders

Light and X-Ray Turbidimetry

Turbidimetry methods are widely used to determine the particle size distribution of refractory metal powders, such as tungsten and molybdenum, and of refractory metal compound powders, such as tungsten carbide. The turbidimeter is standardized in ASTM B 430. Because turbidimetry is used for refractory metals and compounds, several additional factors must be considered to obtain reproducible size and size distribution data. The particles of fine refractory metal powders are often agglomerated by sinter bonds. In ASTM B 430, determination of particle size distribution of the powder is described in the as-supplied condition and after deagglomeration by rod milling (laboratory milling). To obtain consistent, reproducible results by turbidimetry, not only the turbidimetric procedure, but also the deagglomeration procedure, must be standardized. Dispersion of the powder in the liquid before turbidimetric analysis must also be standardized.

Figure 1 shows a typical turbidimeter. The procedure for determining particle size distribution of refractory metal powders with this instrument is included in ASTM B 430. A sample of powder dispersed in a liquid is poured into a glass cell and allowed to settle. A collimated beam of light is passed through the cell at a level having a known vertical distance, h , from the liquid level. The intensity of the light beam is determined by the current generated in a photocell. The current is passed through a potentiometer, where the voltage drop across it is measured by a recording millivoltmeter.

Fig. 1 Schematic of turbidimeter

The reading of the millivolt recorder for the intensity of the light beam shining through the clear solution is adjusted to 100%, while the concentration of the suspension is adjusted so that the reading for the intensity of the light beam through the suspension before any settling has occurred ranges from 20 to 40% of that through the clear solution. As the suspension settles, the projected area of the particles in the suspension decreases, and the intensity of the light beam increases.

At the beginning of the settling, all particle sizes are uniformly distributed through the volume of the sedimentation cell. As settling proceeds, large particles settle faster than small particles. After a given time (t_x), all particles larger in diameter than x have settled below the level of the light beam. The concentration of particles at the light beam level is now equal to the original concentration of particles, minus all particles with diameters equal to or larger than x . The projected surface of the particles at time, t_x , is therefore smaller than that of the particles in the original suspension, and the intensity of the transmitted light is greater.

Determination of Particle Size Distribution. To obtain information on particle size distribution from the plot of light intensity versus time, use is made of the relationship between the total weight of n particles of size x , which is proportional to nx^3 , and the projected surface area of the n particles, which is proportional to nx^2 . Therefore, the cumulative weight of particles up to a given particle size x_{lim} , which is:

$$\int_0^{x_{lim}} dW$$

is proportional to

$$\int_0^{x_{lim}} x dS$$

which is the integral of the product of particle size and projected surface area integrated from 0 to size x_{lim} .

Turbidimetric measurements using white light are relatively inexpensive and have proven quite reproducible and useful. They are used in research and in routine analyses for comparing different lots of refractory metal powders. These methods generally are used for comparative work on the same type of material.

When x-rays instead of white light are used to determine particle size distribution of a subsieve particle suspension, the attenuation of the x-ray beam intensity is proportional to the mass of the powder particles rather than their projected area.

Sedimentation Methods for Classifying Metal Powders

Roller Air Analyzers

This apparatus determined the particle size distribution of metal powders by suspension in a stream of air. Using this apparatus, a powder is classified into particle size fractions that range from 5 to 40 μm . A stream of high-velocity air flowing through a nozzle of suitable size impinges the powder sample contained in a U-tube, so that the powder becomes dispersed within the stream. The velocity (v) of the air stream through the chamber balances the settling velocity of particles with diameter and density determined by a Stokes law calculation:

$$v = 29.9 \times 10^{-4} \rho x^2$$

where v is the velocity of the air stream, cm/s; ρ is the particle density, g/cm³; and x is the particle diameter, μm .

Given this velocity, particles with a size smaller than x are carried through the settling chamber into the collecting system, which consists of an extraction thimble. Larger particles fall back into a U-tube. By using a series of vertical settling chambers with diameters in the ratio 1 to 2 to 4 to 8 and a constant volumetric rate of flow, the powder could be classified into particle size fractions with the maximum sizes in a ratio of 1 to 2 to 4 to 8 (for example, 5, 10, 20, and 40 μm). As previously noted, this sedimentation is no longer in use.

Sedimentation Methods for Classifying Metal Powders

Other Sedimentation Methods

Besides gravity sedimentation, other methods of particle size measurement also employ the Stokes principle.

Andreasen's Pipette. In the pipette method of size analysis, the concentration changes that occur within a settling suspension are followed by using a pipette to draw off definite volumes. Stokes's law is used to calculate the size distribution.

In photosedimentation, a narrow horizontal beam of parallel light is projected through a suspension at a depth, h , onto a photocell. In a homogeneous suspension, if the particles are allowed to settle, the number of particles that leave the light beam will be balanced by the number entering it from above. However, after the largest particle, D_m , in the suspension has fallen from the surface to the measurement zone, the emergent light flux will begin to increase, because no more particles of this size will enter the measurement zone from above. Hence, the concentration of particles in the light beam at any time, t , will be the concentration of particles smaller than D_{st} , where D_{st} is given by the Stokes equation (Ref 3). The particle size distribution is calculated from the relationship between the attenuation of the light beam and the projected surface area of the particles.

X-Ray Sedimentation. Similar to the use of a light beam, x-rays can be used in combination with the gravity settling of particles. In this case, x-ray density is proportional to the weight of the powder in the beam:

$$I = I_0 \exp (-BC)$$

where B is a constant and C is the concentration of powder in the beam. The x-ray density, X_d , is defined as:

$$X_d = \log_{10} \left(\frac{I}{I_0} \right)$$

The sedigraph is a well-known instrument based on the gravitational settling and x-ray absorption analysis. This instrument automatically presents the cumulative percentage frequency, and the sedimentation cell is driven in such a way that the concentration is recorded directly as a function of the Stokes' diameter. The x-rays from a 22.6 keV source are collimated into a narrow beam and pass through a fixed thickness of suspension. The sedimentation cell (Fig. 2) is filled and emptied with the suspension by a built-in pump. The transmitted radiation is detected as pulses by a xenon-filled scintillation detector. The counting electronics give a voltage that is proportional to the powder concentration. Particle size distribution is calculated by the application of Stokes' law to these data.

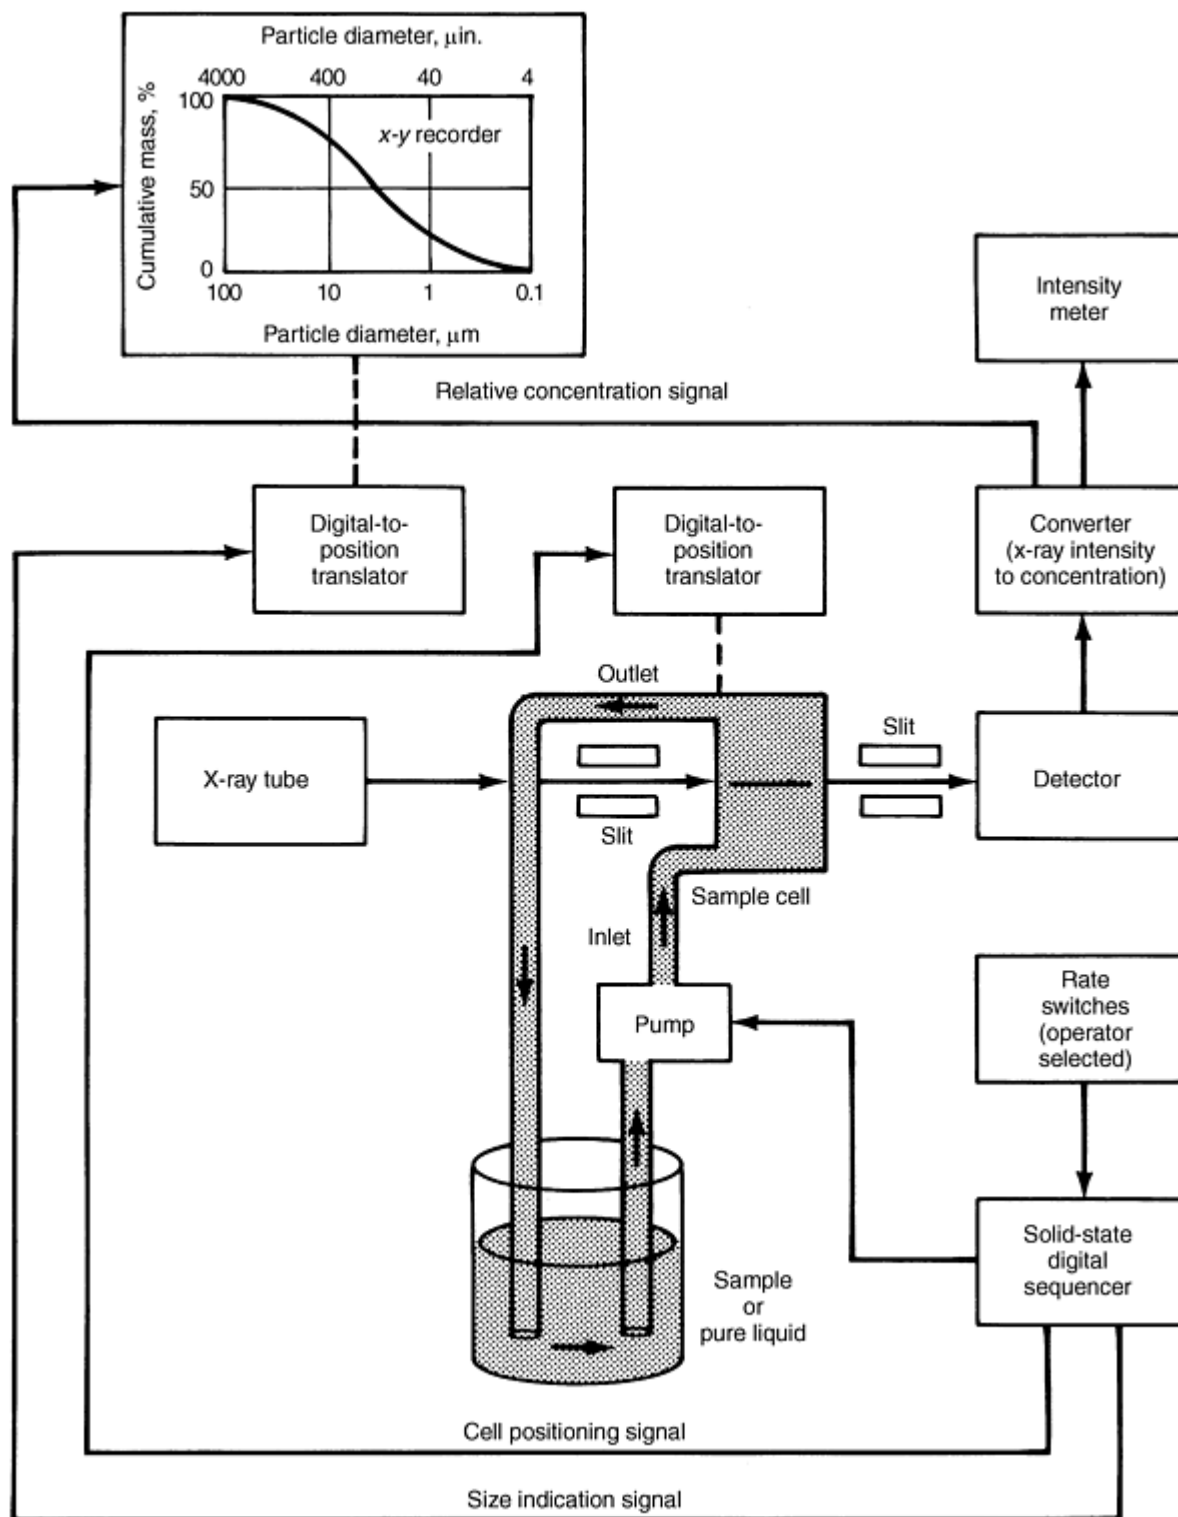

Fig. 2 Sedigraph schematic

Centrifugal Techniques. Because the centrifuging process speeds up the rate of settling of particles, it overcomes one of the serious disadvantages of the gravitational sedimentation techniques, which take an unduly long time for particles $< 5 \mu\text{m}$ ($200 \mu\text{in.}$). In addition, most sedimentation devices suffer from the effects of convection, diffusion, and Brownian motion. Centrifugal sedimentation can be carried out by either a two-layer or homogeneous suspension technique, either cumulatively or incrementally. The two-layer techniques give rise to streaming, a phenomenon most likely to affect cumulative analyses, in which the fraction sedimented against time is determined (Ref 2).

Electric and Optical Sensing Zone Analysis of Powders

Introduction

PARTICLE SIZE MEASUREMENTS by sensing zone analysis are based on dynamic/Stokes principles. These methods are not widely used for metal powders, but they are used for ceramic powders. The two main methods are electrozone (electrical sensing zone) size analysis and optical sensing zone size analysis.

Sensing zone methods involve the suspension of powders in a liquid medium, and there are important factors to be considered when interpreting particle size distribution results for metal powders. Most metal powders have a higher specific gravity than the particulates for which the obscuration-principle apparatus, as well as other particle size analyzers, was originally designed. As a result, a greater tendency exists for particles to settle in the sample reservoir before being sampled, thus causing the distribution to be skewed toward the fine side. This phenomenon is greater for coarser and more regularly shaped particles. Good reproducibility of a distribution does not guarantee the absence of particle settling, as settling of coarse particles also occurs and is reproducible.

Electric and Optical Sensing Zone Analysis of Powders

Electrozone Analysis

Electrical sensing zone analysis is based on the Coulter principle. This method determines the number and size of particles suspended in an electrolyte by causing them to pass through a small orifice with an electrode immersed on either side. The changes in resistance as particles pass through the orifice generate voltage pulses with amplitudes proportional to particle volumes. In this method, the size limits can be extended from 400 to 0.6 μm (16 to 0.024 mils), using a multiple tube technique. An advantage of the method is its independence from particle density, which allows powder mixtures to be sized.

The electrozone method detects the volumes of individual particles in a liquid suspension from the electrical pulse amplitudes that represent individual particle volumes. The pulses are processed via microcomputer to yield particle size

distribution data in whatever form may be required. Figure 1 shows the main components of a computerized electrozone system.

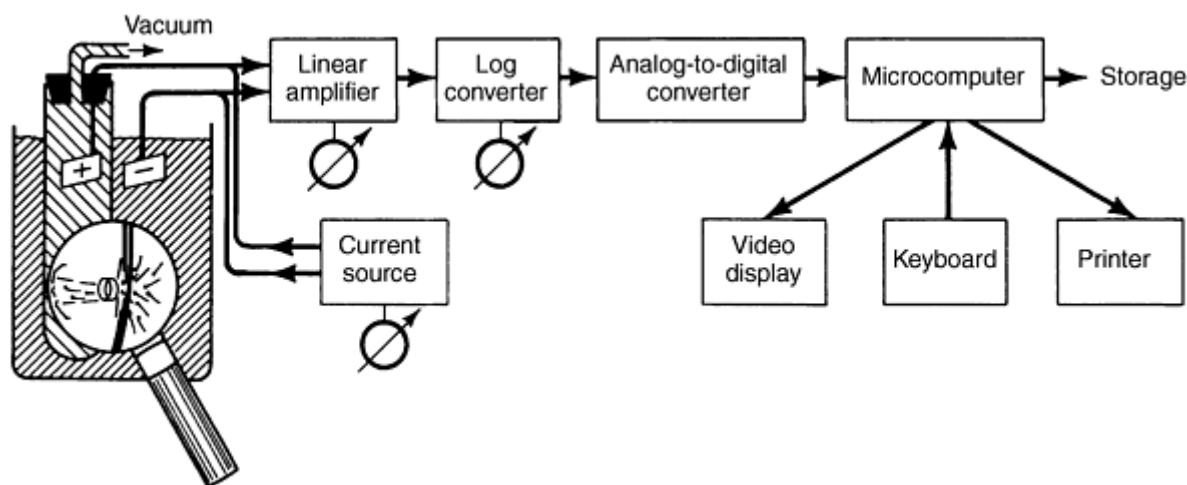

Fig. 1 General schematic of key instruments in an electrozone system

The powder to be evaluated is suspended in a conducting liquid. The suspension is circulated through a sampling chamber, which contains a sensing orifice with immersed electrodes on either side. Within the sensing orifice, particles displace the electrolyte to cause a resistance change (and consequently a voltage pulse) proportional to the "electrical envelope" volume. Because this voltage pulse is independent of particle shape, diameter is expressed as that of a sphere of equal volume, or equivalent spherical diameter.

The size distribution measured by a given testing setup depends on orifice diameter, orifice current, amplifier gain, and logarithmic distribution. The latter provides a distribution selection from 2 to 3% up to 50 to 75% of the orifice diameter, which is full range for a given orifice. Overall, the electrozone method is capable of measuring particle diameters ranging from 0.1 to 2000 μm , depending on particle density. For wide distributions, the computer program can blend data sets, which is facilitated by logarithmic scales.

Collection of size distribution data normally requires several minutes and consists of transfer of the digitized values for many thousands of particle pulses to their proper locations in computer memory. The initial data format is thus a frequency histogram, usually of 128 channels.

Data processing includes smoothing, scale normalizing or converting (both size and quantity axes), marking, editing, extrapolating and blending, subtracting, and creating ratios. Throughout data acquisition and processing, a videoscope display provides interactive, operative monitoring of data and associated items.

Sample preparation requires a particle-free, filtered electrolyte. Many electrolytes have the required characteristics to adequately test various materials. Powdered metals are best analyzed by aqueous solutions of common salts, such as sodium or potassium phosphates (basic) or chlorides, sulfates, or nitrates (neutral). Electrolyte conductivity (strength) may be approximately 2000 mmho/orifice diameter (1% sodium chloride conductivity is ~ 20 mmho/orifice diameter).

Anionic or nonionic dispersants are also used, sometimes with ultrasonic dispersants as needed. Solvating organic electrolytes are available for oily samples. To avoid excessive spurious pulses from coincidence in the sensing zone, sample concentration is limited to 1 to 50 ppm by volume, depending on distribution and shape of the size distribution.

Metal Density. Metal powders have relatively high density, which limits the maximum particle size for uniform electrozone sample suspension. Even if the suspension has efficient agitation and high viscosity (50% glycerol, for example), electrozone data generally will not be acceptable if the particle size-density function exceeds 500, expressed by:

$$(d_m)|\rho - \rho_0|^{-1.5} > 500$$

or

$$(D_m)_{\max} \leq 500|\rho - \rho_0|^{-1.5}$$

where d_m is diameter, μm , and ρ and ρ_0 are densities of particle and liquid, respectively. Typical values are:

Density, g/cm ³	2	5	10	17
d_m (max), μm	500	62	19	8

Below a value of 100 for this function, sieving becomes increasingly effective. Thus, some samples may require both sieve and electrozone analyses, with blending of the two data sets in the overlap region of 100 to 500 for this size-density function.

Metal Conductivity/Magnetism. The oxide surface layer present on most metal particles causes them to appear to be nonconductive, in effect creating a barrier impedance. Electrozone currents high enough to produce 1 to 3 V across the surface layer overcome this barrier impedance, thus causing conduction for only part of the pulse cycle (prior to the occurrence of sulfur polarization and ion depletion). Consequently, the particle pulse will erroneously appear to be smaller.

This effect can be detected by test observation of the total relative volume of particles per unit volume of suspension with increased current value. Samples may be treated with coating reagents or surfactants to increase surface layer impedance. Orifice current settings then must be kept below the level where this effect appears. Similarly, porous particles appear to be too small, due to the conductance of the pores aligned with the electric field, unless they are plugged with nonconductive material.

Magnetic powders may be dispersed for a sufficient time to permit electrozone measurement if they are degaussed for 20 min at temperatures as high as 750 °C (1380 °F) (but below the sintering point, however) and/or spatulated with viscous honey to inhibit reagglomeration. A microscope slide covered with the honey suspension is then dipped into the electrolyte in the stirred sample beaker. In this manner, data acquisition is initiated instantly, while the suspension is being formed from the dissolving honey.

Advantages. The electrozone method rapidly measures particle size distribution with excellent low-end sensitivity and with good resolution (volume response) and precision (minimal side effects).

By contrast, photozone (photicsensing zone) methods, which include light-beam scattering, blockage, and diffraction, have much lower resolution and precision. This is due to their area response and several significant side effects, including photic properties of particles, high coincidence levels, and beam/sensor instabilities. Sieving and sedimentation methods have similar limitations to response and side effects and are much slower in producing data.

Electric and Optical Sensing Zone Analysis of Powders

Optical Sensing Zone

The light blockage principle (obscuration) was used by Carver in 1958 to develop a method for counting and sizing particulate contamination in hydraulic fluids (Ref 1, 2). To date, this principle has found application in other particle-fluid systems and has been used for the measurement of metal powder particles.

In an apparatus using the light-obscuration principles, particles are suspended in a fluid with a refractive index that differs from the refractive index of the particles. The suspension is then passed through a restricting orifice--the sensing zone--across which a collimated white light beam passes. Figure 2 illustrates the sensing zone. The beam of light falls on a photodetector, which measures the intensity of the light passing through the zone.

Fig. 2 Sensing zone for (1 to 45 μm) particle sensor based on light obscuration

Large particles block the light beam, thus lowering the intensity with which the beam strikes the sensor. Small particle sizes ($<3 \mu\text{m}$) do not block the light rays; the rays bend around the particles. The sensor can be designed so that a slight bend that is equal to an index of refraction change of 0.05 causes the light to miss the detector, thereby detecting particles.

Instrumentation. Figure 3 is a schematic of the particle size analyzer based on the obscuration principle. The suspension is prepared in the reservoir cup, which is equipped with a stirrer. A vacuum pump pulls the suspension up through the sampling tube and through the sensing zone located in the back of the sampler stand. Once analyzed, the suspension is collected in a waste chamber.

Fig. 3 Schematic of particle size analysis apparatus based on light obscuration

The sensing zone is designed to prevent laminar flow, which causes each particle to tumble through the zone. The sensor output is a voltage signal, which is proportional to the amount of light blocked by a particle at a given instance, superimposed on a constant baseline voltage. The height of the pulse generated above the baseline as a particle traverses the sensing zone is proportional to the particle's largest cross section.

The relationship between the size of the particle and amplitude of the pulse produced can be determined theoretically. In practice, however, calibrated spheres are used to determine this relationship and to calibrate the sensor (Ref 3, 4). Sensors are available in the following particle size ranges:

- 1 to 45 μm
- 1.5 to 67.5 μm
- 2 to 90 μm
- 2.5 to 112.5 μm
- 5 to 225 μm
- 10 to 450 μm
- 16.7 to 750 μm
- 41.7 to 1875 μm
- 150 to 6750 μm

The first five ranges are the most useful for studying metal powders used in the P/M industry. The actual sensor dimension (height in Fig. 2) is one- larger than the largest particle size for which the sensor is rated; consequently, sensor blockage is minimized (Ref 3, 4).

The microprocessor scales the sensor output pulses and sorts them into 23 size ranges, or channels, in a geometric progression of 1 to 1.18 by using 24 analog comparators. Within the limits of the physical size of the sensing zone, the thresholds can be adjusted to change the widths of the channels to provide more or less detail of certain areas of the particle size distribution, or to extend the range slightly. The threshold adjustment circuits are housed on a printed circuit board that is changed when the sensor is changed to monitor a new particle size range, for example.

The system memory accumulates the number of pulses generated between each pair of thresholds, and the central processing unit reduces the data, calculates the output data, and controls the printer and plotter output functions.

Accuracy and Interpretation. Instrument-related factors must be considered, even with perfectly dispersed, spherical particles (Ref 5). The oversized particle indicator has another purpose in addition to detecting large particles that exceed the range of the sensor--it indicates an overconcentrated solution. If several particles overlap while passing through the sensor, the oversize indicator flashes, and the oversize counter is incremented. If this tendency occurs frequently (more than once or twice per analysis), the solution may need to be diluted, or the sensor may be blocked. If dilution does not eliminate the oversize indication, but does reduce its frequency by an amount proportional to the dilution, the large particles are most likely part of the actual distribution.

Even if dilution eliminates the oversize indication, small particles may overlap and skew the distribution toward the coarse side. To eliminate this occurrence, a maximum recommended number of particles per cubic centimeter of liquid is given for each sensor. High-concentration sensors that allow twice the concentration to be analyzed by restricting the volume of fluid, and therefore the occurrence of two particles in the sensing zone at the same time, are available.

To increase detail in some parts of the distribution and to extend the analysis range, channel thresholds can be adjusted. Adjustable thresholds, however, can slip out of adjustment. The appearance of a sharp peak and an adjacent dip in the same place on several different derivative distributions may indicate the need for threshold adjustment. When this condition occurs, counts are being placed in the channel above or below the proper one. For the cumulative percent under or over distributions, the effect is cancelled when both of these channels are passed. Threshold adjustment can be performed with a printed circuit extender board and a digital voltmeter. The overall detection level of the instrument should be checked periodically using calibrated spheres.

Settling of particles in the sample reservoir can be reduced by using a more viscous fluid such as glycerine. Pure glycerine, however, may be too viscous for the vacuum to draw and also may prevent the dispersion of particles that tend to agglomerate. Glycerine can be thinned with water, but antissettling benefits are diminished.

A more effective way to eliminate settling is to use reservoir shapes, such as round-bottom beakers, and stirrer configurations that maximize turbulence and prevent "dead" spots in the stirring current, without the generation of foam or bubbles that appear as particles in the sensor. Even if reservoir suspension is ideal, particle settling can still occur in the sampler tube (the tube connection between the reservoir and the sensor).

The higher the linear velocity of the fluid, the larger the size of the particles that can be entrained and carried along. The linear velocity of the fluid in the sampler tube is determined by the rate of flow through the restricted sensing zone and by the diameter of the sampler tube. The small sensor has a smaller sensing zone; consequently, the flow rate through the sampler tube is lower, causing the larger particles to settle before reaching the sensor. This tendency can be controlled by fitting the sensor with a smaller sampler tube. This increases the linear velocity of the fluid and keeps the larger particles entrained.

Small particles may have a tendency to loosely agglomerate due to moisture, or van der Waal's forces, for example. Stirring the water suspension of such a powder may be only partially successful in separating these particles. Addition of a surfactant or type IC dispersing aid to the powder before water is added helps the water wet the particles and allows them to separate with the stirring action. Ultrasonically vibrating the solution for several minutes also helps separate particles.

Effect of Lubricants. Many metal powders for P/M use are prelubricated by the powder manufacturer. Typical lubricant additions range from 0.5 to 1.0 wt%. While the presence of lubricants or other chemical additives or particle surfaces may inhibit wetting and cause agglomeration, lubricants have another significant effect. Lubricants or other chemical additives are much less dense than metal particles. Consequently, a small amount of lubricant by weight may contribute greatly to the particle count (population) distribution.

When the volume distribution is calculated from the population distribution, the small amount of lubricant (by weight) is weighted the same (per particle) as the metal powder. In this case, the volume distribution is not the true weight distribution. The same occurs during the analysis of a powder mix in which the constituents have different specific gravities. Single-component powders provide the best test results, unless only the population distribution is desired. Powders should be unlubricated, or the lubricant should be removed prior to analysis.

Light Scattering Measurement of Metal Powders

Michael C. Pohl, Horiba Instruments, Inc.

Introduction

LIGHT-SCATTERING measurements are capable of providing particle-size analysis on a broad range of particle sizes in a rapid, convenient fashion. Current technology is capable of measuring from several tens of nanometers to several millimeters in less than one minute. The instruments have proven themselves capable of solving a variety of problems associated with the production and handling of these powders.

Previous versions of these instruments had much more limited size range capabilities (Ref 1). The advent of modern microprocessors has led to the development of more advanced hardware and software designs. These advances have led to many new features that can be beneficial to the user of the equipment. Table 1 lists some of the more important benefits. The positive benefits have led to increasing use of this technique.

Table 1 General features of light-scattering particle-size analysis

Feature	Possible range of features	User benefit
Expanded range	0.02-2000 μm	More types of samples can be analyzed
Automatic analysis	Autosampler for 24 samples	Unattended operation of the instrument
Dry analysis	Samples can be run wet or dry	Samples can be run as they are normally used
PC control of the instrument	All standard programs, such as Windows, can be used	Easy storage, retrieval, and analysis of data
Flexible analysis of data	Narrow modes, multimodes, or broad distributions can be analyzed	Broader range of samples can be analyzed quickly
Mie scattering equations can be used	More complicated algorithms are used to analyze data	More correct particle size data are presented

Light-scattering instruments are now capable of determining subtle differences in distributions that are not reflected in a change of the median size of the distribution (Ref 2). In many cases these subtle changes can be correlated to a change in the performance of the particles of interest. This is an important characteristic of the generated data. As correlations are understood and are related back to the processing conditions in the plant, knowledge is gained about process variations. This knowledge can be used in process control and is one reason for the continuing use of the technique.

Light Scattering Measurement of Metal Powders

Michael C. Pohl, Horiba Instruments, Inc.

General Theory

The general theory of light scattering was developed in the early 1900s (Ref 3) while practical application occurred somewhat later (Ref 4). The fundamental concept is the Mie theory (Ref 5), a complete equation that explains the scattering phenomenon. In the past this was difficult to use, and simplifying assumptions were made. The most common assumption is that the particles are opaque, circular obstructions in the beam of light (Ref 6). This allows the Mie equation to be simplified to Fraunhofer diffraction theory. This greatly reduces the amount of input data and the complexity of the calculations to be performed. However, it does have a cost. The accuracy of particle-size measurements (especially for small-sized particles with size approaching that of the wavelength of the incident radiation) is lowered when the Mie equation is simplified in this way.

Modern computers make it possible to easily solve the more complex Mie equation. Figure 1 represents this equation. A number of the parameters are determined by the design of the system and are constants. These include λ and R . Other variables are refractive indices (μ_1 and μ_2), which also must be known to ensure accurate measurements.

Light scattering intensity obtained from Mie theory

$$K(\theta, m, D) = \frac{\lambda^2}{8\pi^2 R^2} [i(\theta, m) + i(\theta, m, D)]$$

$\alpha = \pi D/\lambda$ Size parameter

D : Diameter

λ : Incident light wave length

R : Radial distance

$$m = \frac{\mu_1}{\mu_2} = \frac{\text{Refractive index of particle}}{\text{Refractive index of dispersing medium}}$$

Fig. 1 Laser-scattering principle. Calculation of scattering intensity based on the Mie theory

Refractive Indices

Refractive indices are well-characterized values for most particle systems. In many cases it is merely a matter of referring to standard reference literature (Ref 7). In some cases there are actual tables that are being prepared by International Standards Organization committees (Ref 8). In the rare example of newly developed materials or mixed dispersant systems, these values can be measured experimentally. In a liquid medium, the values could easily be measured by a refractometer. These are available from a number of commercial vendors. In the case of particles, the measurement can be performed by a microscopic-immersion method.

Microscopic-Immersion Method. In this approach the particle is immersed in a liquid of known refractive index, and the medium refractive index is matched to the solid in a trial and error approach. This approach is best described in the following paragraph (Ref 9):

"The refractive index of any solid may be determined microscopically by successfully immersing fine particles of the solid in liquids of known refractive index until, in one such liquid, the particles become invisible. When this occurs, the refractive index of the invisible particles must be identical with that of the liquid medium in which they are immersed. Similarly, the index of the solid may be determined by varying the index of the mounting liquid until it matches that of the solid and then measuring the index of the liquid. The index may be varied by mixing liquids, by varying the temperature and/or the wavelength of light and by dissolving varying amounts of solid in a liquid."

Becke Test. The microscopic-immersion method can be a very slow laborious task if the selection of fluids is done in a totally random fashion. Fortunately there are approaches available to accelerate this process. The most popular approach is the Becke test, where the Becke line is a bright halo near the boundary of a transparent particle that moves with respect to that boundary as the microscope is focused up and down. The halo will always move to the higher refractive index medium as the position of focus is raised. The halo crosses the boundary to the lower refractive index medium when the microscope is focused. The particle must be illuminated with a narrow cone of axial light, which may be obtained by closing the iris diaphragm of the condenser until only a small aperture remains (Ref 9).

Absorptive Component of Refractive Index. The real component of the refractive analysis can be found or measured. Unfortunately in the case of the particles, there is typically also an imaginary or absorptive component. As Annex IV (Ref 8) shows, this term has also been determined in the case of many particles. In the event it is not known, there are several analytical techniques that may be used (Ref 4). Beyond these approaches, there are also empirical approaches that may be used (Ref 10). Thus by a variety of approaches, the liquid and solid refractive index can be determined. The relative refractive index is then determined by dividing the value for the particle by that for the liquid. This value is then input to the instrument for determination of the particle-size distribution.

Light Scattering Measurement of Metal Powders

Michael C. Pohl, Horiba Instruments, Inc.

Instrument Design

A typical laser light-scattering instrument consists of a light source, a particle-dispersion and delivery system, a detector to measure the scattering pattern, and a computer to control the system and determine the particle-size distribution. Older instruments were only capable of measuring the scattering pattern at low angles ($<20^\circ$) and were limited to measuring particles $>1\ \mu\text{m}$. More modern instruments collect scattering information at more and larger angles. This can be accomplished by the use of a converging beam, more or larger lenses, a second light-generating system, or the use of more detectors. This allows particles $<0.1\ \mu\text{m}$ to be measured accurately. These newer developments form the basis for this new description of light-scattering measurements (Ref 8).

Figure 2 shows the typical configuration for a laser-diffraction instrument. In the conventional setup, a laser is used to generate a monochromatic, coherent, parallel beam. A beam processing unit, usually a beam expander with an integrated filter, produces a beam to illuminate the dispersed particle collective. The direct, unscattered beam is then measured by the obscuration detector. The sample is passed through the laser beam in the measuring zone. The scattered light encounters the Fourier lens which focuses the scattered beam and eliminates the scatter from inappropriate particles. The focused scattered light is then collected on the multielement detector. This light represents the information that is processed to determine the particle-size distribution.

Fig. 2 Example of a laser diffraction instrument setup

This type of system can be compared to the new designs available. Figure 3 shows a good example of such a system. In the heart of such a system is the more conventional laser system that is measuring the forward scattering from the larger particles. In this particular arrangement, the helium-neon laser is also being used to measure the scattered-light intensity at a variety of narrow angles. A second optical system featuring a tungsten lamp is also incorporated. It is filtered to a much shorter wavelength and is optimized to measure the light scattered at very wide angles. This is an ideal system for measuring the smallest particles.

Fig. 3 Flow schematics

Several other features are prominent in Fig. 3. Dispersion and proper delivery of particles are critical to the success of these newer instruments. Because they analyze a broad range of sizes (0.02 to 2000 μm), the pump must be capable of delivering particles uniformly to the laser beam. Also because many particles, especially small ones, tend to agglomerate, dispersion of the sample plays a key role. The powerful, ultrasonic probe is incorporated into this system to meet that challenge. Another key area is the addition of new components to better control the feed of the sample into the instrument. In this case an auto sampler and auto reservoir unit are shown as optional to this system. Improving instrument performance of these units is the focus of new development. As a result, the units are discussed in a later section.

Algorithm Calculations

The hardware of the system allows measurement of the scattered-light intensity at a series of different angles with several different wavelengths. This information is then used in a series of algorithms to calculate the particle-size distribution. Figure 4 shows the basic equation governing this relationship. This emphasizes the idea that several more pieces of information must be available to solve for the desired result ($f_j(D)$). There are two general approaches to solving this problem.

$$g(N) = \sum_{j=1}^m K(N, D) f_j(D) \Delta D$$

$g(N)$: Output from the N th detector

$K(N, D)$: Response function of the N th detected volume

$f_j(D)$: Particle size distribution based on volume

D : Typical particle size

ΔD : Interval between particle sizes

(a) Accumulation of scattered light at the detector

(b) Relationship between the scattering intensity, $g(N)$, of the scattered light accumulated at the detector and the particle size distribution, $f(D)$

Fig. 4 Relationship between position of the detector and scattering intensity, $g(N)$

The older approach, called the matrix method, is illustrated in Fig. 5. When the Lagrange method is applied, the $f(D)$ can be determined. This method suffers from a number of limitations that have caused it to fall from favor. The limitations include problems with accuracy on monodispersed samples, the ability to properly recognize multimodal samples, and susceptibility to electronic noise in the system. As a result, a newer approach was developed. This method was developed from the solution of a somewhat unrelated analytical problem (Ref 10). This method, shown in Fig. 6, is called the iteration method.

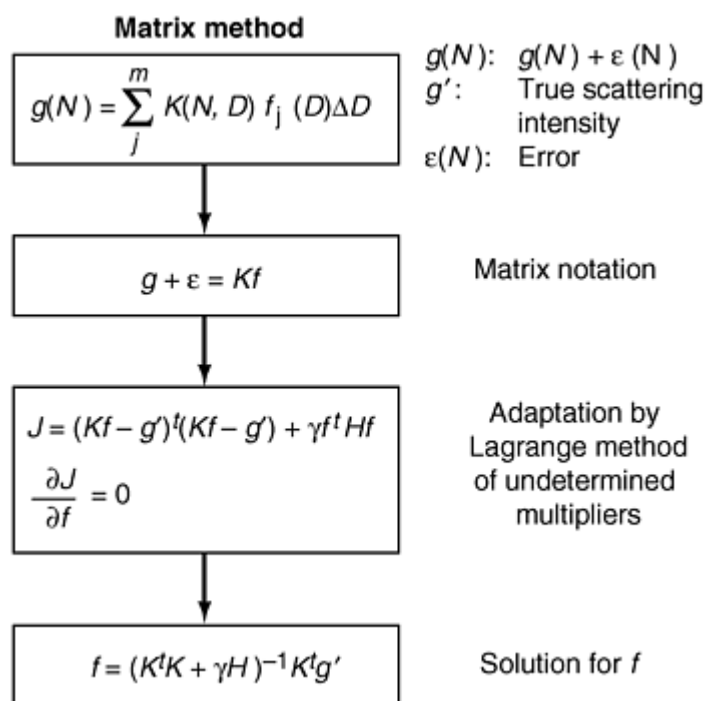

Fig. 5 Calculation of the particle-size distribution, $f(D)$, by the matrix method

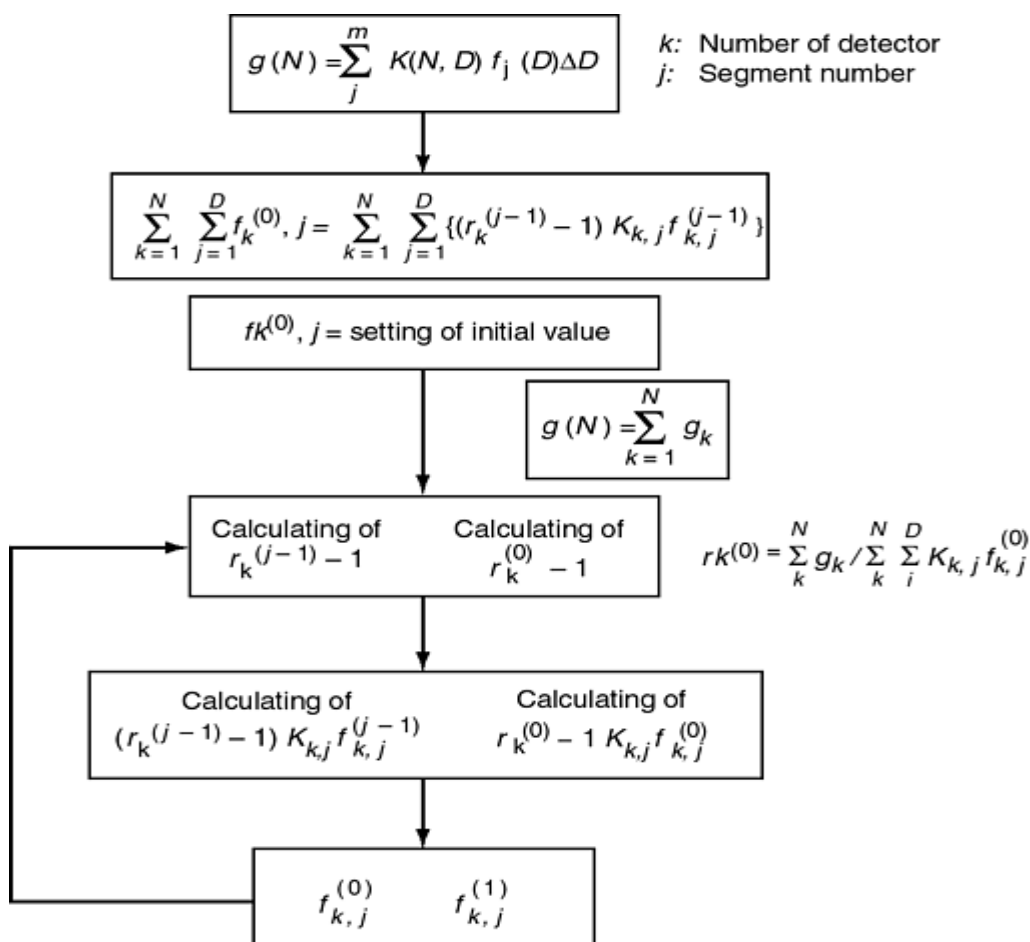

Fig. 6 Calculation of the particle size distribution, $f(D)$, by the nonlinear iteration method

Figure 7 shows a schematic representation of the steps involved in the iteration method. This method works by constantly comparing the measured scattering pattern to the proposed theoretical particle-size distribution. As more iterations are performed, this difference A , sometimes called χ^2 should become progressively smaller. As this happens, the calculated particle-size distribution becomes ever closer to the true value. While this process is repeated, the attempt is made to reduce it to zero. Practically this does not happen, so criteria for an acceptable A value is established, and the iterations are stopped at that point. Control over the number of iterations is determined depending upon the system being analyzed.

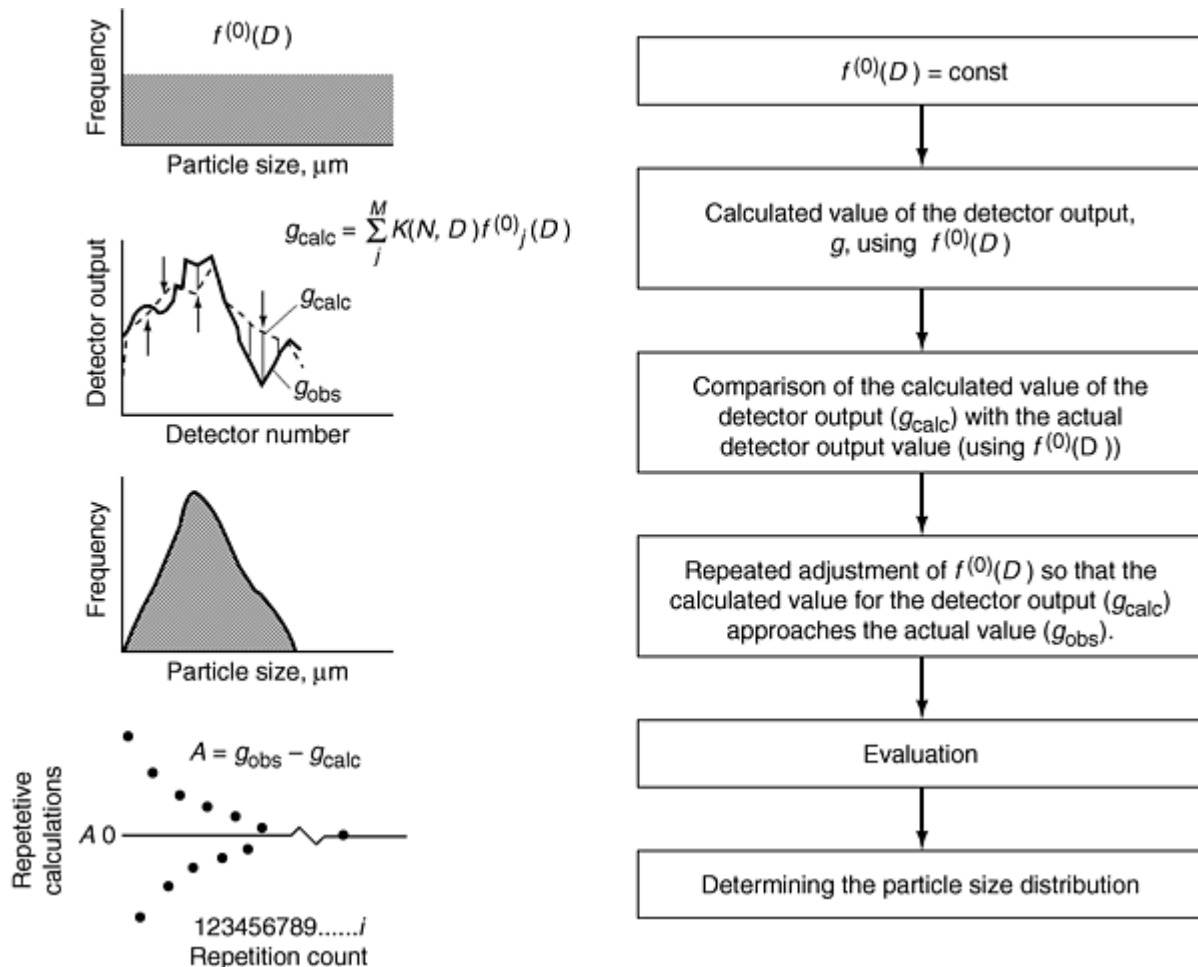

Fig. 7 Schematic representations of the steps involved in particle-size distribution, $f(D)$, by the nonlinear iteration method

In this analysis, the missing major component is the relative response of each size particle at each detector. Figure 8 illustrates this problem. This relative response must be taken into account to properly solve for the particle-size distribution. A generalized approach has been to calculate a kernel function for a well-characterized system and then apply it to the equation to solve for $f(D)$. A very common starting point is to use a series of well-characterized polystyrene latex (PSL) samples. These samples are available in a wide variety of sizes and have been sized by a variety of techniques, including microscopy. From the known information, plus the fact that the relative refractive index is $(1.59 - 0.00i)/1.33$, it is possible to calculate the response factors.

Light Scattering Measurement of Metal Powders

Michael C. Pohl, Horiba Instruments, Inc.

New Applications

The basic physics of the light-scattering process have been understood for quite some time. Instrument design using this technique has enabled measurement of particles >5 orders of magnitude in size. As the size range has rapidly reached its theoretical limitation, other issues have become paramount. These issues include proper introduction of the sample into the laser beam, proper dispersion of the sample prior to analysis, the introduction of more exotic samples into the beam, and automation to simplify and extend the use of technology. These issues have come to the forefront recently and are expected to remain critically important in the future.

Improved Pumping Systems. One of the primary issues in a laser light-scattering experiment is presenting a representative sample to the laser for analysis. In most cases only a very small fraction of the sample can be measured at any given time. As a result this is a prime issue to consider, as larger and larger particles are being analyzed. These developments have caused the pumping system to be treated as a separate module that is added to the analysis system. In many cases, older peristaltic pumps that were used for particles in the several hundred micrometer range, have had to be replaced. A variety of approaches to this problem have been implemented.

One of the most popular approaches has been to incorporate a centrifugal pumping system. A typical example of such a pumping system is shown in Fig. 9. This type of pump provides adequate power to pump even $2000\ \mu\text{m}$ particles around the system in a uniform, smooth fashion. Similar systems are incorporated into all newer instruments.

Fig. 9 LA-920 pumping system

Another different approach is to totally remove the pumping module from the system. This option typically works only with smaller particles as the larger particles tend to become sediment below the laser beam. In spite of this limitation, this approach is very good for analyzing particles in obnoxious fluids. It minimizes the use of the solvent and simplifies the retrieval of the sample. The approach has proven useful in the analysis of a variety of particles, including emulsions and polymers.

Dispersion Accessories. The major obstacle to measuring an accurate, reproducible particle size is dispersion. In older instruments this need was typically not met by the analyzer. It was assumed that dispersion would be performed external to the instrument. The instrument was designed to handle stable, well-dispersed particles only. This, however, required a large laboratory space to house the instrument and the auxiliary equipment needed to disperse the sample. It also meant that the fundamental particle size could not be determined for less stable dispersions. These issues and the desire for quick, simple analysis procedures led to the incorporation of the dispersion accessories into the instrument.

A typical example of this is seen in Fig. 9. In this system, the powerful ultrasonic probe is placed directly into the stream of flowing liquid. This forces the particles to impinge directly on the tip of the horn and helps to maximize the energy of the imploding bubbles to effect the best possible dispersion of the sample. It is also a great aid in removing bubbles prior to the introduction of the sample. The rapid flow rate and its position immediately in front of the cell where the laser beam is focused make it possible to analyze even strongly agglomerating samples. Variable power outputs and duty cycles make it possible to handle even delicate particles. These accessories have greatly expanded the range of samples that the instrument can analyze.

Dry Analysis. Many particles are prepared dry and remain dry in their end use. These particles include, in some cases, pharmaceutical tablets, food products, dry pigments, and airborne particulates. In these cases, the introduction of a fluid medium serves to complicate matters significantly, because it introduces serious constraints on the analysis. A variety of dispersion liquids for the laser diffraction method are available. They should:

- Be transparent at the laser wavelength (e.g., for HeNe 633 nm)
- Be compatible with the materials used in the instrument (O-rings, tubing, etc.)
- Not dissolve or swell the particulate material
- Favor easy and stable dispersion of the particulate material
- Have a known refractive index that differs significantly from that of the particulate material
- Have low or medium viscosity to enable recirculation
- Not be hazardous to health and safety

Wet Dispersion. When working in the wet state, many aids are available to assist in the dispersion of the sample. The presence of large numbers of solvent molecules aids in dispersion, and often the separation effect of the liquid is augmented by the use of viscous media. For some examples, dispersants or surfactants are added to the liquid to improve dispersion. In many cases, shear energy or ultrasonic energy are applied to aid in the dispersion. In the dry phase, none of these approaches are applicable, so a totally different approach has to be taken. These technologies have greatly advanced in the last several years.

Dry Dispersion. Figure 10 (Ref 8) illustrates three approaches for dry dispersion. The two basic approaches of collisions and shear stress use very different technology to address dispersion. In the two collision methods, it is assumed that the energy of the collision is transferred to the breaking of the "bonds" holding the particles together. In cases where the particles are hard and not susceptible to fracture, this may work. In some cases the energy is used to break the individual particles instead. In the use of velocity gradients, the force is typically less violent and less prone to fracturing particles. This has come to be the most accepted approach for dispersing dry particles.

(a)

(b)

(c)

Fig. 10 Process involved for dry dispersion of powders. (a) Velocity gradients caused by shear stress. (b) Particle to particle collisions. (c) Particle to wall collisions

Figure 11 illustrates the principle of operation. The desired velocity gradient is produced by the introduction of compressed air to the vacuum stream at the jet nozzle. The shock of going from a vacuum condition to >80 psi in a short distance provides the desired force. Usually this is sufficient energy to disperse the samples.

Fig. 11 Powder jet systems

Comparison of Wet and Dry Analysis. The increasing popularity of dry analysis has caused comparisons of wet and dry analysis. In countless cases, these two analyses have produced comparable results. In cases where differences have persisted, issues have been identified to explain the differences. In some cases, powders have flowed so poorly that they could not be fed properly. The addition of a small amount of silica enabled proper feeding of the material. In the case of strongly agglomerated particles, the particles actually behaved that way in the dry process. As a result, the dry, agglomerated results were actually more correct. Despite problems with dry dispersion, dry analysis is a firmly established technique.

Automated Features. Most of the automation that has been developed to date has been in the area of wet analyses. This can be seen in areas such as the simplification of the analysis through personal computer (PC) programs or the use of sophisticated programs to allow one button analysis. Automatic alignment of the optical bench of the instrument is also a feature. Although these are important developments, they typically make operation more convenient but not necessarily faster. The major improvement in this area has been in the form of automated feeding of the sample or the liquid used to dilute the sample. These systems can take on a variety of configurations depending on the type of sample that is being analyzed.

Liquid feeding can be achieved through a variety of mechanisms. In the simplest configuration, a container of fluid is placed at a high elevation and allowed to flow into the instrument. In most cases, a source of fluid at a positive pressure fluid is available to introduce the liquid at an appropriate rate and in a correct volume. Reservoir systems also afford the opportunity to select a variety of liquid and surfactants to be fed into the instrument. This versatility increases the speed of sample preparation, sample analysis, and sample clean up.

Sample feeding is a major innovation for automation. A variety of configurations are available and perform quite differently. The best systems are those that are specifically designed for particle size analyzers rather than those that are "borrowed" from a gas chromatograph or similar analyzer. In specially designed systems, different samples are fed to the instrument, and a scheduler program allows for many types of experiments to be run. These include dispersion curves,

kinetic studies, stability experiments, reproducibility tests, etc. All of these can be completed in an unattended fashion with increased time savings and sample throughput.

On-Line Analysis. Typically, the sample is in a jar or beaker for analysis, which means an operator mechanically withdrew the sample to be analyzed. This is an extra step requiring additional time and effort and is a possible source of additional error. To overcome these issues, laser light-scattering instruments also are used for on-line process analysis (Ref 12). While this marks the evolution of all analytical technologies, it is a very recent development in the particle sizing arena.

Historically the acceptance of this technology for plant use has been limited by many problems. They include the lack of ability to obtain a representative sample, lack of ability to keep the sample dispersed, lack of adequate cleaning for the instrument, and lack of ruggedness in the instrument design. Recently these problems have been solved for some of the well understood and better behaved processes. Many discussions of this analysis are now encountered in the literature (Ref 13). On-line analysis of dry powders is becoming more common. Examples of on-line measurement of wet systems also are becoming quite common (Ref 15).

Future Developments. In the past 10 to 12 years, an explosive growth has occurred in the popularity of laser light scattering as a technology for performing particle-size analysis. This popularity has led to the development of many new features and capabilities. The range of analysis has been greatly expanded as have the types of samples that can be analyzed. The analysis has been automated, and the reproducibility and repeatability have been improved. Even the algorithms used to determine the particle size have been improved. There are some indications that it can be used routinely in an on-line application. All of these trends are expected to continue well into the future. As new types of particles are developed and new particle systems are introduced, adaptations will develop to feed them to a laser light-scattering instrument to measure the particle size.

Time of Flight Measurement of Metal Powders

Brian H. Kaye, Department of Physics and Astronomy, Laurentian University

Introduction

THE GALAI INSTRUMENT is one of the first time-of-flight instruments used to characterize the size of powder grains (Galai Production Ltd., Ha Hameak, Israel). For a time this instrument was widely sold in the United States by the Brinkmann Company, so it is sometimes referred to as the Brinkmann size analyzer. Figure 1 shows the basic principles of the Galai instrument. Light from a laser is focused to a fine beam, and the beam is rotated by the rotating optical wedge. As the laser tracks a circular path in the cell containing the particles to be characterized, the size of the profile is measured by the time required for the laser beam to track across the profile of the powder grain. The instrument determines when a particle is intercepted at its maximum width, and it is calibrated using standard fine particles. The instrument also incorporates a video camera to view the particles being characterized at right angles to the rotating laser (Ref 1).

Fig. 1 Galai particle size analyzer. (a) Basic layout of the Galai instrument. (b) Laser beam tracing a circular path within the cell and the logic of the instrument rejecting any particles that are off center or out of focus. (c) Laser beam blocked from reaching the photodetector

Figure 2 demonstrates the accuracy of the time-of-flight, or time-of-transit method, by the agreement in the measurement of the powder-size distribution measured by the Galai instrument, with the known size distribution of a standard powder prepared and distributed by the European Commission on Standard Materials, Brussels, Belgium. The sample studied in Fig. 2 is BCR-67.

Other Time-of-Flight Measurement Systems

Another system that uses time-of-transit measurements to obtain particle size information is manufactured by Lasentec (Ref 2). This system is often used in on-line monitoring of material. Figure 3 shows the basic system used in their equipment. In technical literature (Ref 2) Lasentec states:

"The focused beam will cross the particle structure on a straight line between any two points on the edge of the structure. The distance between two points is a chord length. Thousands of chords are typically counted per second. The number of chords measured over a specific time period are sorted by chord length into a 38 channel distribution. The resulting chord length distribution tracks changes in particle geometry, a function of the shape and dimension of the particles, and particle structures as they naturally exist in process."

Fig. 3 Lasentec focused beam reflectance measurement system

Two time-of-flight instruments that study the size of fine particles in the aerosol format are available from TSI Inc., St. Paul, MN, and Amherst Process instruments Inc., Amherst, MA. Figure 4(a) shows the basic system of the instrument manufactured by TSI, known as the aerodynamic particle sizer (APS) analyzer. After the powder to be characterized is made into an aerosol, the aerosol is fed into the equipment. As shown in the Fig. 4(a), some of the aerosol under study is filtered to create a clean air sheath, which confines the aerosol being created to the center of the measurement zone. The two laser beams are $125\ \mu\text{m}$ apart and $\sim 200\ \mu\text{m}$ downstream from the nozzle orifice. The air feed to the interrogation zone is used to accelerate the particles, which respond to the accelerating forces at varying rates depending on their mass. The time-of-flight between the two laser beams is measured and used to calculate the particle velocity. The instrument is able to measure particles in the region of 0.5 to $30\ \mu\text{m}$. The instrument is calibrated using standard polystyrene spheres. Figure 4(b) shows typical results for the instrument.

Fig. 4 The TSI aerodynamic particle sizer. (a) Basic layout. (b) Results from a mixture of three sizes of polystyrene latex spheres. (c) Results for a therapeutic aerosol

The parameter of the powder grains measured by this instrument is known as the aerodynamic diameter of the particles. The aerodynamic diameter of a particle is defined as the size of a sphere of unit density having the same velocity as the particle under the same flow conditions. This aerodynamic diameter differs from diameters measured in other methods of particle size, and data need to be interpreted in a knowledgeable manner. Several publications deal with the relationship between particle sizes measured by time-of-flight and other well-known methods of size analysis, such as microscope image analysis and diffractometers (Ref 3).

The TSI Inc. system works at subsonic velocities and uses one photocell. In 1994, TSI Inc. announced an advanced version of their instrument, the Model 3320 aerodynamic particle size spectrometer, using double crested optics. TSI Inc. claims that the new model sizes particles from 0.5 to 20 μm aerodynamic size and can operate at 1000 particles/cm³.

Figure 5 shows the system used in the Aerosizer, manufactured by Amherst Process Instruments Inc. Note that one of the problems in using instruments such as a time-of-flight aerosol spectrometer is ensuring that the powder under study is efficiently dispersed as an aerosol (Ref 4). The Amherst instrument has an auxiliary piece of equipment, the Aero-Disperser, for dispersing powders that enable the investigator to vary the shear rate applied to the powder being aerosolized (Fig. 6). The equipment is used to carry out investigations of various shear rates applied to powder as it is aerosolized, until further increase in the shear rate does not result in a difference in distribution measurements. The aerosol being interrogated is surrounded by sheath air as the particles under study are accelerated into the interrogation zone. As shown in Fig. 5, the interrogation zone differs from that of the APS equipment in that two photocells are used to measure the optical energy scattered by the particles as they move through the two beams. A sophisticated electronic editor distinguishes which signal arriving at the photodetectors is associated with the initial signal from a given particle as it enters the first laser beam. The Aerosizer operates at sonic velocities and can count fine particles at a very high rate. The equipment measures the aerodynamic diameter and is calibrated using particles of known size. The output can be either a measure of the number of particles of a given aerodynamic size (Fig. 7a) or as a transformation into geometric size by volume (Fig. 7b). The geometric size by volume is a transformation of the aerodynamic diameter and takes into account the density of the particles being measured.

Particle Image Analysis

Introduction

MICROSCOPY is the most definite method of particle size analysis, because individual particles are observed and measured. However, optical and electron microscopy also afford the opportunity for particle shape analysis. Particle shape, like particle size, is a primary powder characteristic that must be considered when determining the optimum utilization of a P/M material. Behavioral characteristics of a metal powder, such as flow rate, apparent density, compressibility, and sinterability, are all influenced by particle shape and size.

This article briefly reviews the common methods of optical and electron microscopy for image analysis of particle size distributions and particle shape characterization. Image analysis of particle size distribution is a very precise quantitative practice, while particle shape analysis is more qualitative in nature. Advancements in qualitative shape analysis are based on the use of the scanning electron microscope for determination of particle shape. In addition to its high magnification capability, this device produces an image with a three-dimensional appearance. Because of its advantages, scanning electron microscopy (SEM) has replaced optical microscopy to a large extent in the area of shape and topographical analyses of metal powders.

Quantitative shape analysis has posed numerous difficulties. However, with the advent of advanced computers and graphics systems, interest in quantitative analysis has increased. Through the use of optical and scanning electron microscopy, qualitative descriptors have been developed to label different particle shapes. As computational technology advanced, mathematical algorithms were written to describe particle shape. Fourier analysis and fractal geometry are two mathematical disciplines that are being applied to describe particle shape. Because of the computational intensity of these disciplines, most of the work has been confined to a two-dimensional space. The current challenge is to develop three-dimensional modeling programs that can accurately describe the shape of irregularly shaped particles.

Image Analysis of Powder Size

Microscopy is a very precise method of particle size analysis, but some of the techniques used are more art than science. However, if the basic principles of sampling, preparation, and counting are followed, a precise count can be made with a thorough understanding of the nature of the particles being studied. ASTM standard E 20 details the use of microscopy for particle sizing.

Particle Image Analysis

Size Measurements

Various techniques are used to measure the size of irregularly shaped particles when viewed through a microscope. This has resulted in different measurements, which are used to classify these two-dimensional particle images in terms of an equivalent spherical particle. Accepted measurements (Fig. 1) include:

- *Feret's diameter (F)*: The maximum length of the particle measured in a fixed direction
- *Martin's diameter (M)*: The length of a line that bisects the area of the particle image; all particles measured in the same direction
- *Project area diameter (d_a)*: The diameter of a circle with the same area as the two-dimensional image of the particle
- *Longest dimension*: The maximum Feret's diameter for each particle: no set direction
- *Perimeter diameter (d_p)*: The diameter of a circle having the same circumference as the perimeter of the particle
- *Maximum horizontal intercept*: The length of the longest line that can be drawn through the particle in a fixed direction

Fig. 1 Techniques for measuring sizes of irregularly shaped particles. See text for identification of variables.

Feret's diameter is the easiest to measure manually. The average Feret's diameter is related to the perimeter of the convex hull of the particle, as shown in Fig. 2, by the relationship:

$$F_{av} = \frac{P_{CH}}{\pi}$$

where P_{CH} is the perimeter of the convex hull. Martin's diameter is related to the specific surface S_v of the particle by:

$$M = \frac{4}{S_v}$$

The projected area diameter gives the best estimate of the true cross-sectional area of the particle.

Fig. 2 Feret's diameter

Generally, the three diameters above are related to one another by the expression $M < d_a < F$. Their ratios remain fairly constant for a given material. The expression F/M has been used as a shape function, which is equal to 1 for spherical particles and increases in magnitude as particle shape becomes more acicular. Perimeter diameter and maximum horizontal intercept (or longest chord) are measured easily by some of the automatic particle sizing analyzers.

Particle Image Analysis

Sampling Techniques

The most important step in any particle size analysis, but especially by microscopic techniques, is sampling from the bulk. Because an extremely small quantity of material is used to determine the particulate size, an accurate analysis cannot be obtained if the bulk material is not properly sampled. Particles tend to segregate according to size. If handling has caused vibration of the sample, coarse material tends to collect near the surface. When free-flowing material is poured into a pile, the coarse portion collects near the outside of the pile, and the fines concentrate in the center. The following sampling techniques are recommended for obtaining a valid representation of particle sizes in a laboratory sample.

Chute rifflers (Fig. 3) consist of V-shaped hoppers that feed a series of chutes, which alternately feed into trays on opposite sides of the hopper. A sample that is properly poured into the hopper is halved, and the process is repeated until a suitable sample size is obtained. Sampling efficiency depends on an even feed of the sample into the hopper and on the width of the chutes. Numerous narrow chutes provide more accurate sample statistics than a few wide chutes, provided the powder can flow easily through them.

Fig. 3 Chute riffler

Spinning rifflers (Fig. 4) divide a sample by feeding it into a number of containers that rotate on a table under the feed. This method is efficient, provided the table rotates at least 100 times during the flow of the sample.

Fig. 4 Spinning riffler

Oscillating Sampler. The feed hopper oscillates rapidly between two sampling cups, thereby halving the sample. Feed times must be long compared to oscillation times for optimum efficiency.

Cone and Cup Sampler. In this device, the sample is fed onto a cone that disperses the powder in all directions along the cone surface. A sample cup is rotated around the base of the cone, gathering portions of the sample at every position. The width of the cup and length of the cone periphery determine the sample reduction.

Sampling tables (Fig. 5) are used to reduce larger quantities of the sample. Sampling tables consist of an inclined plane with a series of holes that halve the sample in each of the four stages, leaving $\frac{1}{16}$ of the original volume as a final sample.

Fig. 5 Sampling table diagram

Cone and quartering involves pouring the sample into a cone-shaped pile on a glass plate, flattening the top, and dividing it into quarters with a thin metal blade. One of the quarters can then be mixed, repoured, and requartered until a suitably small sample is obtained. This method requires some technique to ensure symmetry of particle sizes in the pile and accurate quartering.

Scoop sampling is the least precise, but perhaps the most frequently used, sampling technique. The sample container is shaken, and a small portion is extracted with a scoop or spatula. However, segregation can be imparted to the sample by the shaking method. The scoop sampling technique that provides the least variance is shown in Fig. 6 and consists of shaking the container back and forth while rotating. Because particle sampling is the initial and most important step in particle size analysis, miniature sampling devices should be used whenever possible.

Fig. 6 Scoop sampling apparatus showing direction of shaking

Particle Image Analysis

Optical Microscopy

The optical microscope is used to count and size particles ranging from 100 to 0.5 μm diameter. The resolution of an optical microscope is optimally about 0.25 μm , but diffraction effects at the edges of small particles result in significant errors in measurements within this size range. Resolution down to 0.1 μm can be improved by using ultraviolet light and quartz optics.

A severe limitation of the optical microscope is its small depth of field, which is about 10 μm at 100 and 0.5 μm at 1000 \times . This requires that the specimen powders be mounted carefully in one plane and eliminates the use of automatic counting devices on samples with wide particle size ranges. Another limitation is that due to the small number of particles usually counted, only the field of view can be characterized, not the entire lot from which the specimen was obtained.

Preparation of slides for optical microscopy is an art, and the quality of a dispersion depends more on the skill of the preparer than on the particular technique used. Care must be taken to prevent segregation of particle sizes and to prevent the formation of agglomerates. Preparation techniques vary with the type of powder and depend on particle size, particle size range, and particle composition. Typical dispersion techniques are described below.

Dry Mounting. When a permanent slide is not required, and the powder exhibits good flow characteristics, slides can be prepared by "puffing" dry powder onto the slide or by applying it with a brush.

Dispersing Fluids. In applications that require shearing action to disperse the powder, a dispersing fluid such as cedar oil or glycerol can be used. The simplest technique involves placing a drop of dispersing fluid on a glass slide and placing a small amount of powder onto the drop. A cover slip is then placed carefully over the mounting fluid and pressed evenly with an eraser, while gently rotating the cover slip back and forth.

Another method involves placing some of the powder on a glass slide, adding a few drops of dispersing fluid, and working the mixture with a flexible spatula or soft brush. More fluid is added until the proper concentration is obtained. A drop of this mixture is then transferred to a new slide and covered with a cover slip.

Permanent Slides. A small amount of powder is placed in a beaker to which 2 or 3 mL (0.07 or 0.10 fluid oz) of a solution of 1 to 2% collodion in butyl acetate is added. The mixture is stirred vigorously, and a drop of the suspension is placed on the surface of distilled water. The drop spreads and forms a thin film as the solvent evaporates. The film is then picked up on a microscope slide and dried.

Other films can be produced by dissolving parlodion in amyl acetate, Canada balsam in xylene, and polystyrene in xylene.

Films are formed by casting a 1% solution on water or a $\frac{1}{2}$ % solution directly on a glass slide. After the films dry, the powder is applied by spraying or by letting a drop of aqueous suspension dry on the surface. The particles sink into the medium, forming a permanent slide. Melted Canada balsam or glycerol jelly also can be used to form permanent samples.

Other Methods. Certain applications may require samples prepared by specialized techniques, such as heating magnetic particles above their Curie points for dispersion. These examples generally serve as guidelines for technique development.

Particle sizing usually is performed indirectly in the optical microscope, because the small depth of field frequently requires refocusing on individual particles. If the size range is narrow and the preparation is carefully made in a single plane, photographs or automatic particle counting devices can be used. Projection microscopes are also available that reduce operator fatigue for analyses that require numerous counts.

Particle Image Analysis

Transmission Electron Microscopy

The transmission electron microscope is used for counting particles that range from 0.001 to 5 μm in diameter. This instrument has a large depth of field; consequently, all particles in the field of view are in focus regardless of size. Particles are usually not counted directly from the viewing screen of the transmission electron microscope. Photographs are normally taken, and counts are made from prints or projected images using the negatives.

The electron beam is easily absorbed, and films greater than 100 to 200 nm (1000 to 2000 \AA) are completely opaque. It is therefore necessary to produce very thin support films on which powders can be dispersed for counting. These films usually are made of carbon. One of the best techniques for producing strong, flat carbon support films involves cleaving high-quality mica and placing it immediately in a vacuum evaporation unit. After a hard vacuum has been obtained, carbon is evaporated onto the mica surface to a thickness of about 10 nm (100 \AA).

Film thickness can be calculated by including a white porcelain slide containing a drop of vacuum oil in the vacuum chamber. When the porcelain that is not covered by the oil appears as a light chocolate shade, the carbon film is about 10 nm (100 \AA) thick. The mica is then removed from the vacuum and slowly lowered at an angle into a beaker of distilled water. The carbon film floats off the mica onto the water surface, where it can be picked up on an electron microscope grid.

Another technique involves casting a thin film of parlodion onto the surface of distilled water by depositing two or three drops of 1% parlodion dissolved in amyl acetate onto a clean glass slide. The slide is allowed to drain and dry, and the film is floated from the slide onto distilled water. The plastic film is then picked up on transmission electron microscopy (TEM) grids, placed in a vacuum evaporator, and coated with carbon.

The parlodion can be carefully dissolved in amyl acetate by placing the grids on a fine stainless steel mesh bridge suspended in the center of a petri dish. Amyl acetate is added to the petri dish until the level of the liquid reaches the bottom of the mesh. The dish is then covered and left for a few hours, after which the grids are carefully removed.

If the parlodion film is thin enough, it can be left on the grids. However, this requires fresh, water-free solutions and care in handling, or holes will form in the thin plastic film as the solvent evaporates. Prepared carbon substrates on grids are available.

Powders are dispersed on the surface of support films by puffing from an aspirator or by allowing a drop of aqueous suspension to dry. Carbon films are hydrophobic; use of an aqueous suspension requires that they be rendered hydrophilic by either treatment with a thin solution of albumen or exposure to reactive oxygen in a low-temperature oxygen asher. Exposure to reactive oxygen must be done at a very low setting (4 W) for several seconds, or the carbon film will be destroyed.

Powders that require additional dispersion can be prepared by placing a small amount of powder on a clean glass slide and adding several drops of 1% parlodion in amyl acetate. This mixture is sandwiched between a second glass slide. As the amyl acetate evaporates, the mixture becomes more viscous. Immediately before the parlodion dries, the slides are sheared apart. This preparation can be viewed in the optical microscope to find the area of best dispersion. This area is then scribed into 3.2 mm ($\frac{1}{8}$ in.) squares and floated from the glass slide onto distilled water. The squares are picked up on electron microscope grids and coated with carbon to add stability to the electron beam.

For some samples that are difficult to disperse, ethylene glycol may be a suitable dispersing agent. A small amount of powder is added to a few drops of this viscous liquid on a glass slide and mulled until a good dispersion is obtained. A carbon substrate grid is then touched to the thin liquid film, which sticks to the grid. The grid is placed in a vacuum chamber and pumped for a few minutes, during which time the ethylene glycol sublimates, leaving the particles on the carbon substrate.

Particle thicknesses can be measured in the transmission electron microscope by "shadowing" particle dispersions in which the particles sit on a substrate and are not embedded in a plastic film. This is done by evaporating a small amount of metal placed at an angle to the substrate surface in a vacuum chamber. The metal coats the surface and particles in a line-of-sight fashion, leaving a "shadow" cast behind the particles. Commercially available precision-sized latex spheres can be included with the powder sample so that the shadow length to particle height ratio can be calculated.

Of the pure metals, platinum is best suited for shadowing because of its fine structure in an evaporated film. About 12 mm (0.5 in.) of 250 μm (10 mil) platinum wire, evaporated from a point source at an angle of 30° and a distance of 100 mm (4 in.), casts a good shadow.

Many other preparation techniques are used to observe powders in TEM, and most analysis methods are modified to suit the application and the operator's ability.

Particle Image Analysis

Scanning Electron Microscopy

The scanning electron microscope has a resolution of about 10 nm (100 \AA) and is capable of very low magnification (about $10\times$) up to about $50,000\times$. It therefore can be used to count particles ranging in size from 1 mm to 0.1 μm . Particles smaller than 0.1 μm usually have too low a contrast with the background to be counted efficiently. The scanning electron microscope has about $300\times$ the depth of field of an optical microscope.

The image in the scanning electron microscope usually is obtained by using the secondary electron output of the sample as it is scanned by a very narrow electron beam. The contrast of the image depends more on the topography of the sample than on differences in atomic number. Therefore, prepared powders must not be embedded in films, but dispersed on a smooth substrate. Any smooth surface can be used as a substrate. However, if energy dispersive x-ray analysis (EDXA) is to be performed for particle identification, a carbon or polystyrene surface is preferred.

An excellent substrate can be made by placing a polystyrene pellet on a glass slide and heating it on a hot plate until it softens. A second glass slide is then placed over this slide and pressed until the pellet forms a thin disk. The slides are removed from the hot plate and pressed together until the polystyrene sets. The disk thus formed is as smooth as the glass and contains no elements that may hinder EDXA. For sample preparations using aqueous suspensions, polystyrene surfaces can be rendered hydrophilic by a brief treatment in an oxygen asher at low power (5 to 10 W for 5 s).

While the substrates for SEM do not have to be as thin as those used for TEM, they must be conductive. Consequently, if glass or plastic surfaces are to be used, they must be coated with an evaporated metal (or carbon, for EDXA) film. This coating is usually applied after the particles have been dispersed on the surface.

Many of the dispersing techniques used for TEM can be applied to SEM. Particle dusting, drying from liquid suspensions, and mulling in liquids that can be sublimed in a vacuum are suitable dispersing methods, depending on the powder. If the technique of mulling in parlodion and amyl acetate is used, parlodion can be removed in an oxygen asher, thus leaving the particles on the substrate. Suitable substrates include glass or metal, because they are not affected by the ashing.

The prepared sample should always be placed in the scanning electron microscope with the surfaces normal to the electron beam so that the magnification, which changes with working distance, will be the same on all areas of the viewing screen. Particle counting can be done directly from the viewing screen, from photographs, or by using an automatic image analyzer.

Particle Image Analysis

Measurement Techniques

Direct Measurements. Particle diameters can be measured directly in an optical microscope with the use of a filar micrometer eyepiece. This eyepiece contains a scale and a movable cross hair that is operated by a calibrated knob on the side of the eyepiece. A particle is moved so that one side touches one of the fixed scale markings, and the cross hair is moved to touch the other side of the particle. The difference between the two readings is the Feret's diameter of the particle. The eyepiece is calibrated with an optical stage micrometer. This technique is time consuming, and because absolute measurements are not required for accurate size analysis, eyepiece graticules are usually used for direct measurements.

Figure 7 shows typical examples of eyepiece graticules. These patterns are etched on glass disks that are positioned in the back focal plane of the microscope ocular and are therefore in the same focal plane as the particle images. Using one of these gauges, the size range, into which the actual diameter of a particle falls, can be measured easily. Feret's diameter, projected area diameter, or perimeter diameter are measured conveniently with graticules. Where measurements are made from photographs, projected images, or cathode ray tube screens, simple scales or plastic overlay graticules can be used to measure any of the accepted diameters.

Fig. 7 Eyepiece graticules

Image shearing eyepieces are used directly within the optical microscope. This device divides the optical beam into two parts by using mirrors and/or prisms. The distance between the two formed images is adjusted by shearing of the prisms, which is controlled by a micrometer dial on the side of the eyepiece. The maximum horizontal intercept is measured when the two images barely touch. With this device, a particle does not have to be moved to a particular position within the field of view to be measured.

The micrometer can be set to a given diameter, and the number of particles larger or smaller than this measurement can be counted, as determined by whether or not the images are touching. Red and green filters facilitate this by coloring the two images.

Semiautomatic Techniques. Many devices are available to shorten the time required to complete a particle size analysis. Most of these instruments record the number of particles in a size range, as judged by the analyst.

Adjustable light spot analyzers use a circle of light projected onto a photograph. The diameter of the circle can be adjusted by a diaphragm; a foot switch causes one of a bank of registers to record the diameter according to the diaphragm setting. Each particle on the photograph is passed under the light, which is adjusted to measure the projected area diameter or the perimeter diameter.

A transparent electronic graticule is a plastic sheet on which various size circles have been drawn. Under each circle, an electrical contact is connected to one of a bank of registers. When a contact is touched by the analyst with a pencil contact, the register advances one number. This device can be used with photographs, back-projected images, and cathode ray tube screens. The analyst decides which circle best represents the diameter of a particle and touches the corresponding contact.

Recording calipers work in the same manner, with a bank of registers connected to the caliper spread adjuster. Any particles of the prescribed diameter can be recorded with this device.

Recording micrometer eyepieces use a similar recording mechanism, but work directly within the optical microscope. Two movable cross hairs that move toward or away from each other with the turn of a micrometer screw are used to bracket a particle; a button is subsequently pushed to record the diameter. This technique is particularly useful when the depth of field prevents photography of the particles, because each particle can be sharply focused before measuring.

Sensitive surfaces connected to computers facilitate counting from photographs. The computer can be programmed to record diameters when the opposite sides of particles are touched with a pointer, or specific areas of the particle are touched. The computer consequently compiles data to suit user requirements.

Automatic techniques are used for counting large numbers of particles directly within the microscope. The main limitations of these techniques are the inability to distinguish particles that are touching and the fastidious sample preparation that is required.

Spot scanning devices use the moving spot from a cathode ray tube, which is projected through the microscope onto the specimen. When the spot passes over a particle, the light beam is interrupted, and a photocell records the particle. Particles are sized by scanning with different spot sizes. This technique also has been used on photographs, so electron micrographs can be used.

The slit scanning method projects the microscope image onto a slit. The microscope slide is mechanically scanned, and the signal produced as the particle images pass the slit is recorded. The width of the slit can be varied to eliminate coincidence and overlap.

Quantitative image analyzers are computer-controlled devices that use television cameras for direct analysis within an optical microscope. Analysis of photographs can also be accomplished. A quantitative image analyzer can be connected directly to a scanning electron microscope to control the scanning system. Particles can be counted according to their maximum horizontal chords, vertical chords, perimeters, or areas.

Data Presentation. Table 1 shows the most precise form of presenting particle size data. However, graphical representations are more concise and visually show the mean and deviation from the mean. Some graphical presentations can yield specific values for descriptive constants such as the mean, median, and the standard deviation.

Table 1 Particle size data

Particle size range, μm	No. of particles	Particles, %	Cumulative percent less than size
1-2	0	0.0	0
2-3	3	0.6	0.6
3-4	8	1.6	2.2
4-5	15	3.0	5.2
5-6	79	15.9	21.1
6-7	163	32.9	54.0
7-8	121	24.4	78.4
8-9	64	12.9	91.3
9-10	28	5.7	97.0
10-20	13	2.6	99.6
20-30	2	0.4	100

A histogram is a bar graph that illustrates the frequency of occurrence as a function of the size range. Figure 8 shows a typical histogram for a log-normal size distribution. The smooth curve drawn through the histogram is a valid size-frequency curve if sufficient particles are counted and the number of size intervals is at least ten.

Fig. 8 Histogram and size frequency curve for log-normal size distribution

In cumulative plots, such as Fig. 9, the median particle size can be noted easily. These plots are made by plotting the percentage of particles less than (or greater than) a given particle size against the particle size.

Fig. 9 Cumulative plot used in determining median particle size

A special grid for plotting size-frequency data was developed so that the resulting curve is a straight line. This grid consists of a coordinate based on probability. Cumulative percentages are plotted on the probability scale against particle size on either an arithmetic or a log scale.

Symmetrical size distributions, characterized by a bell-shaped size-frequency curve symmetrical to a vertical line through the mode (apex) point, plot as a straight line on arithmetic-probability paper. Most natural particle distributions do not follow this normal probability, but follow a skewed or log-normal distribution. These distributions provide a symmetrical size-frequency plot if the particle-size scale is logarithmic and forms a straight line on log-probability paper. The median particle size is found at the 50% point on these probability plots, and the standard deviation for arithmetic-probability plots can be calculated as:

$$\sigma = 84.13\% \text{ size} - 50\% \text{ size} \\ = 50\% \text{ size} - 15.87\% \text{ size}$$

and for log-probability plots can be calculated as:

$$\sigma = \frac{84.13\% \text{ size}}{50\% \text{ size}} = \frac{50\% \text{ size}}{15.87\% \text{ size}}$$

Particle Image Analysis

Particle Shape Characterization

Brian H. Kaye, Department of Physics and Astronomy, Laurentian University

Figure 10 shows a typical scanning electron micrograph of an array of iron particles for the type of powder grains encountered by the powder metallurgist in various areas of technology. Many of the techniques for characterizing the shape of powder grains make use of image analysis using pictures such as that shown in Fig. 10(a) (Ref 1). When an array of fine particles to be characterized is inspected, the first thing to be done is to decide what constitutes a separate powder

grain. The economics of taking photographs using an expensive scanning electron microscope require working with a relatively dense field of view, which creates pseudoagglomerates from random juxtaposition. Thus, for the field of view shown in Fig. 10(a), the decision was made that the dashed lines represent separations between individual grains, which are close to each other.

Fig. 10 Iron powder grains illustrate the type of shape characterization problems facing powder metallurgists. (a) Electron micrograph of an iron powder. Source: D. Alliet, Xerox Corporation. (b) Erosion of an image can be used to separate particles.

Several commercial instruments are available for automated image analysis. Some automated image analysis systems have built-in logic procedures known as erosion logic. This procedure enables the device to strip ribbons of pixels away from an image to separate contiguous profiles to allow juxtapositioned particles to be evaluated as separate entities. Figure 10(b) shows the operation of erosion logic to separate profiles for subsequent image analysis. The software used in the work reported here was a program in which a television camera was used to obtain images through a light microscope.

The simplest method for characterizing the shape of profiles such as those shown in Fig. 10(a) is to evaluate what is known as geometric shape factors. In many cases, studies are carried out using fundamental measures on a set of profiles,

such as those of Fig. 10(a), which are assumed to be in a position of maximum stability on the support system when they are photographed.

It should be noted that three-dimensional measurements on powder grain profiles can be used if the image is shadow cast with either evaporated metal or light illumination used in an appropriate manner. Thus, Fig. 11 shows a set of pieces of material as they might have been viewed by an optical microscope. The profiles are illuminated at a given angle to create shadows shown in the diagram (Ref 2).

Fig. 11 Three-dimensional shape information determined by creating an image of a set of fine particle using shadow casting techniques.

The British Standards Institute has prepared a standard glossary of terms for use in the description of the appearance of powder grains (Ref 3):

- *Acicular*: Needle shaped
- *Angular*: Sharp edged or roughly polyhedral shaped. (Polyhedral derives from poly, meaning many, and hedra, meaning a base; therefore, polyhedral is understood to be a geometric shape having many faces, each of which can act as a base.)
- *Crystalline*: A geometric shape freely developed in a liquid
- *Dendritic*: A branched crystalline shape
- *Fibrous*: Regularly or irregularly threadlike
- *Flaky*: No formal definition in the British Standards. (It is assumed that a flaky fine particle is recognizable.)
- *Lamellar*: Platelike
- *Granular*: Approximately equidimensional but irregularly shaped
- *Irregular*: Lacking any symmetry
- *Modular*: Rounded, irregularly shaped
- *Spherical*: Globular shaped

The pioneer work on the development of shape factors was carried out by Heywood (Ref 4, 5, 6) and Hausner (Ref 7). Figure 12 shows the length, width, and thickness of a powder grain, as defined by Heywood. Using these measures, Heywood defined the elongation ratio as the length divided by breadth and the flakiness ratio as the breadth divided by thickness. Extensive reviews of procedures for deriving shape indices from geometric measurements have been prepared by Phal et al. (Ref 8) and Loveland (Ref 9).

$$\text{Aspect ratio} = \frac{\text{Width}}{\text{Length}} = \text{Elongation}$$

$$\text{Chunkiness} = \frac{\text{Length}}{\text{Width}}$$

$$\text{Flakiness} = \frac{\text{Width}}{\text{Length}}$$

Fig. 12 Geometric shape indices defined on the basis of the magnitude of measurements made, either directly on the powder grain, or on images of the powder grains

Three-dimensional measurements of sugar grains have been used to develop three-dimensional graphs of a shape population variation within a powder (Ref 10).

The original shape factors described by Heywood are not currently in widespread use. They have, to some extent, been displaced by the aspect ratio and chunkiness, both of which are defined in Fig. 12. Figure 13(a) shows the simple silhouettes of the profiles shown in Fig. 11. Figure 13(b) shows the aspect ratio distribution for this population of profiles. When the population of aspect ratios are plotted in this way, it appears that there are two Gaussian populations of shapes in the powder. When plotted as a distribution function, the link of shape with size is lost in the calculation of the distribution of aspect ratios. In populations containing a wide range of shapes, the aspect ratio is not always useful, because in theory, it can vary from 1 to ∞ , whereas the chunkiness can vary only between 0 and 1. In the graphical display known as the chunkiness-size domain, the shape of each profile can be plotted, as shown in Fig. 13(c). This type of plot retains the information on shape and size for each profile. Thus from the data display of Fig. 13, the technologist can see immediately that the shape increases with fineness of the powder, information that is not retrievable from Fig. 13(b).

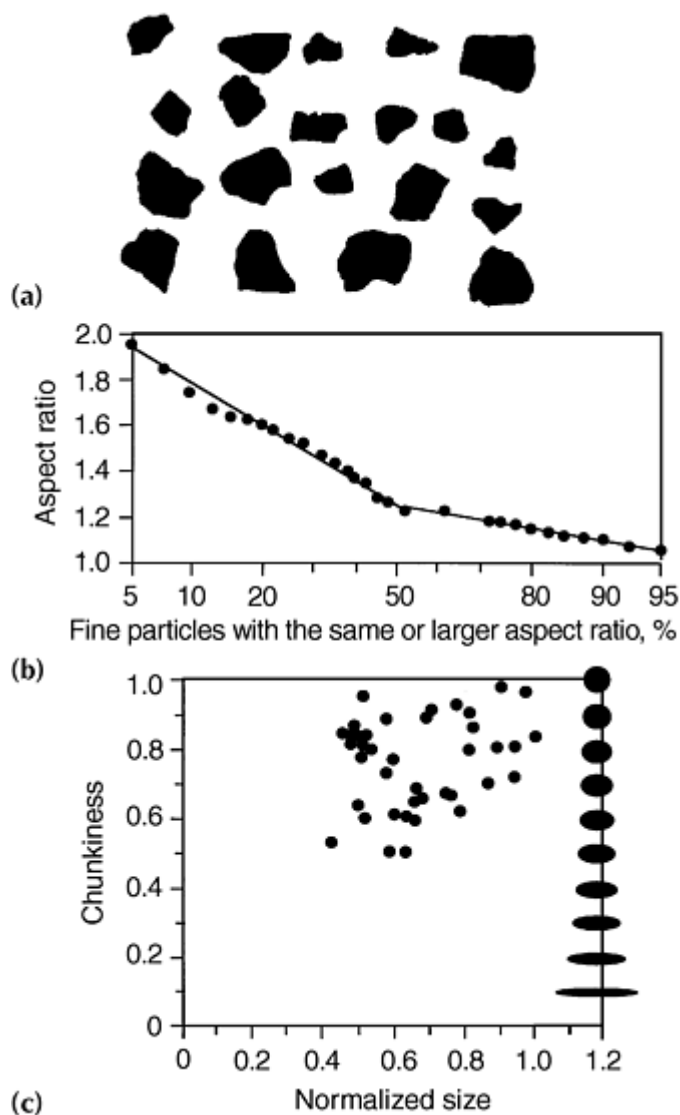

Fig. 13 Shape of fine particles can be characterized by aspect ratio or its reciprocal, chunkiness. (a) Silhouettes of the fine particles shown in Fig. 11. (b) Aspect ratio distribution of a larger set of a fine particles like those of (a). (c) Chunkiness-size domain for the profiles describe in (b)

Figure 14 shows the chunkiness size domain for the powders shown in Fig. 10(a), as determined by image analysis. This data display shows that powder is bimodal in size distribution. This probably arises from the fact that because the powder is magnetic, some fine powders were clinging to the coarser grains when the powder was made by a sieve fractionation process.

Fig. 14 Chunkiness-size domain summary of data generated by image analysis of the iron powder of Fig. 10 demonstrates a bimodal distribution indicating that the powder was probably sieved and that the smaller fine particles were most likely clinging to the larger fine particles.

If measurements are carried out using the dimensional information obtained by shadow casting the images, a triangular grid can be used to plot the three-dimensional information on the profiles. Figure 15 illustrates the way measurements are made on the three-dimensional structure of a grain and then turned into a graphical display. To numerically quantify the scatter of data points on such a diagram, the points in space can be treated as unit masses. The centroid and the moment of inertia can then be calculated as a measure of the range of shapes present in the powder. Although several descriptions of this technique exist, no publications describe how to use such a population of shapes and relate it to the functional behavior of a powder (Ref 11, 12).

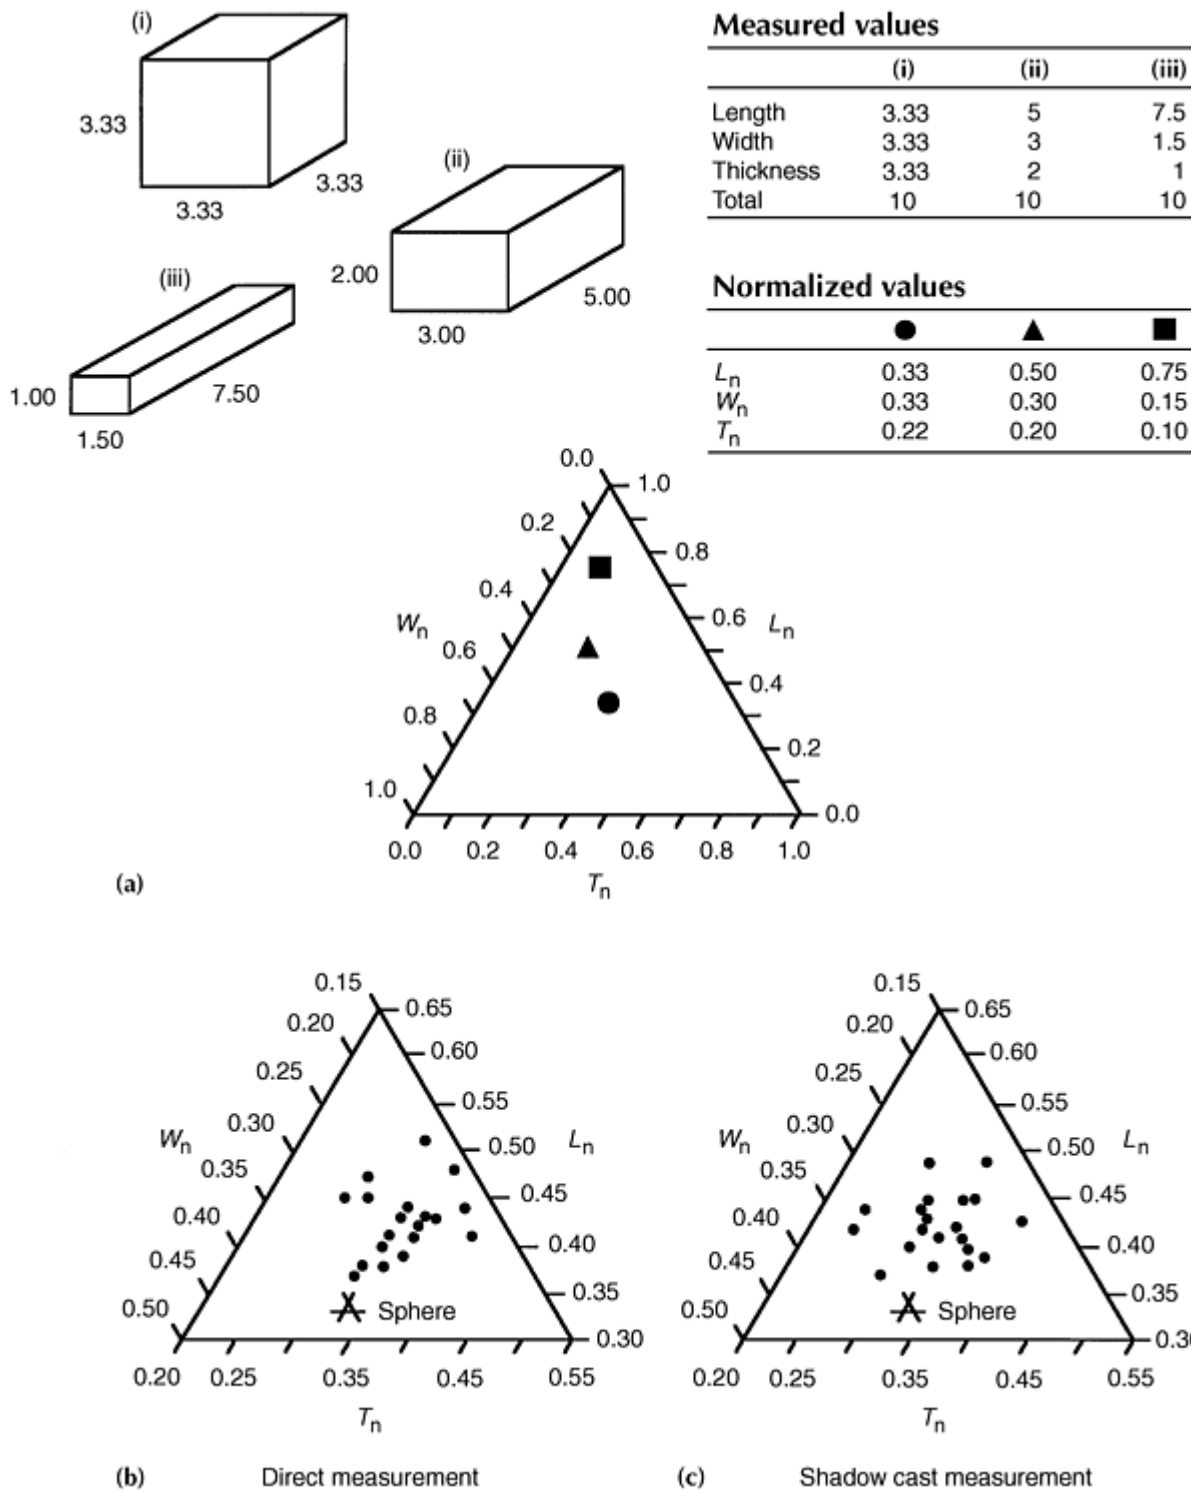

Fig. 15 Three-dimensional shape of a fine particle summarized using triaxial graph paper. (a) Demonstration of the use of triaxial graph paper to plot the dimensions of simple shapes. (b) Direct measurement of the three dimensions of the particles of Fig. 11. (c) Dimensions of the particles of Fig. 11 using shadow casting to determine the third dimension

The gross shape information about a particle grain embodied in a geometric shape factor will govern the packing properties of a powder and is an important parameter to be considered because it contributes to the flow properties of a powder. When the surface reactivity of a powder and its sinterability is considered, the surface structure of the powder grains needs to be quantified.

Fourier Analysis. One method of characterizing the shape and texture of a powder grain is to generate and analyze what is known as the geometric signature waveform of a powder grain (Ref 13, 14, 15). A two-dimensional profile of the particle grain is needed to generate a geometric signature waveform. In one of the more frequently used techniques, the centroid of the profile viewed as a laminar shape is chosen as a reference point. The magnitude of the vector of the series of angles as shown in Fig. 16(a) is then recorded. The high resolution recording of the vector shows that the pattern generated by the rotated vector has the appearance of a complex wave, known as the signature waveform of the profile shown in Fig. 16(b). If the signature waveform is treated by Fourier analysis, the power spectrum of the waveform contains information on the shape and the texture of the profile. Flook (Ref 15) has analyzed the profile in Fig. 16 and shown that the first 5 harmonics of the Fourier analysis describe the gross shape of the profile, whereas the strength of the harmonics from 5 to 25 describe the texture of the profile as shown in Fig. 16(c) and 16(d). The use of signature waveforms and Fourier analysis were pioneered by Beddow et al. in the study of metal powder grains (Ref 16). Difficulties arise in choosing this straightforward geometric signature waveform if the profile of the particle has deep indentations, because in this situation the vector does not have a unique value crossing over the indenture in the profile. This can be overcome in modern data processing by creating the Fourier transform of the actual profile directly on computer logic, but this has not been widely used in powder metallurgy.

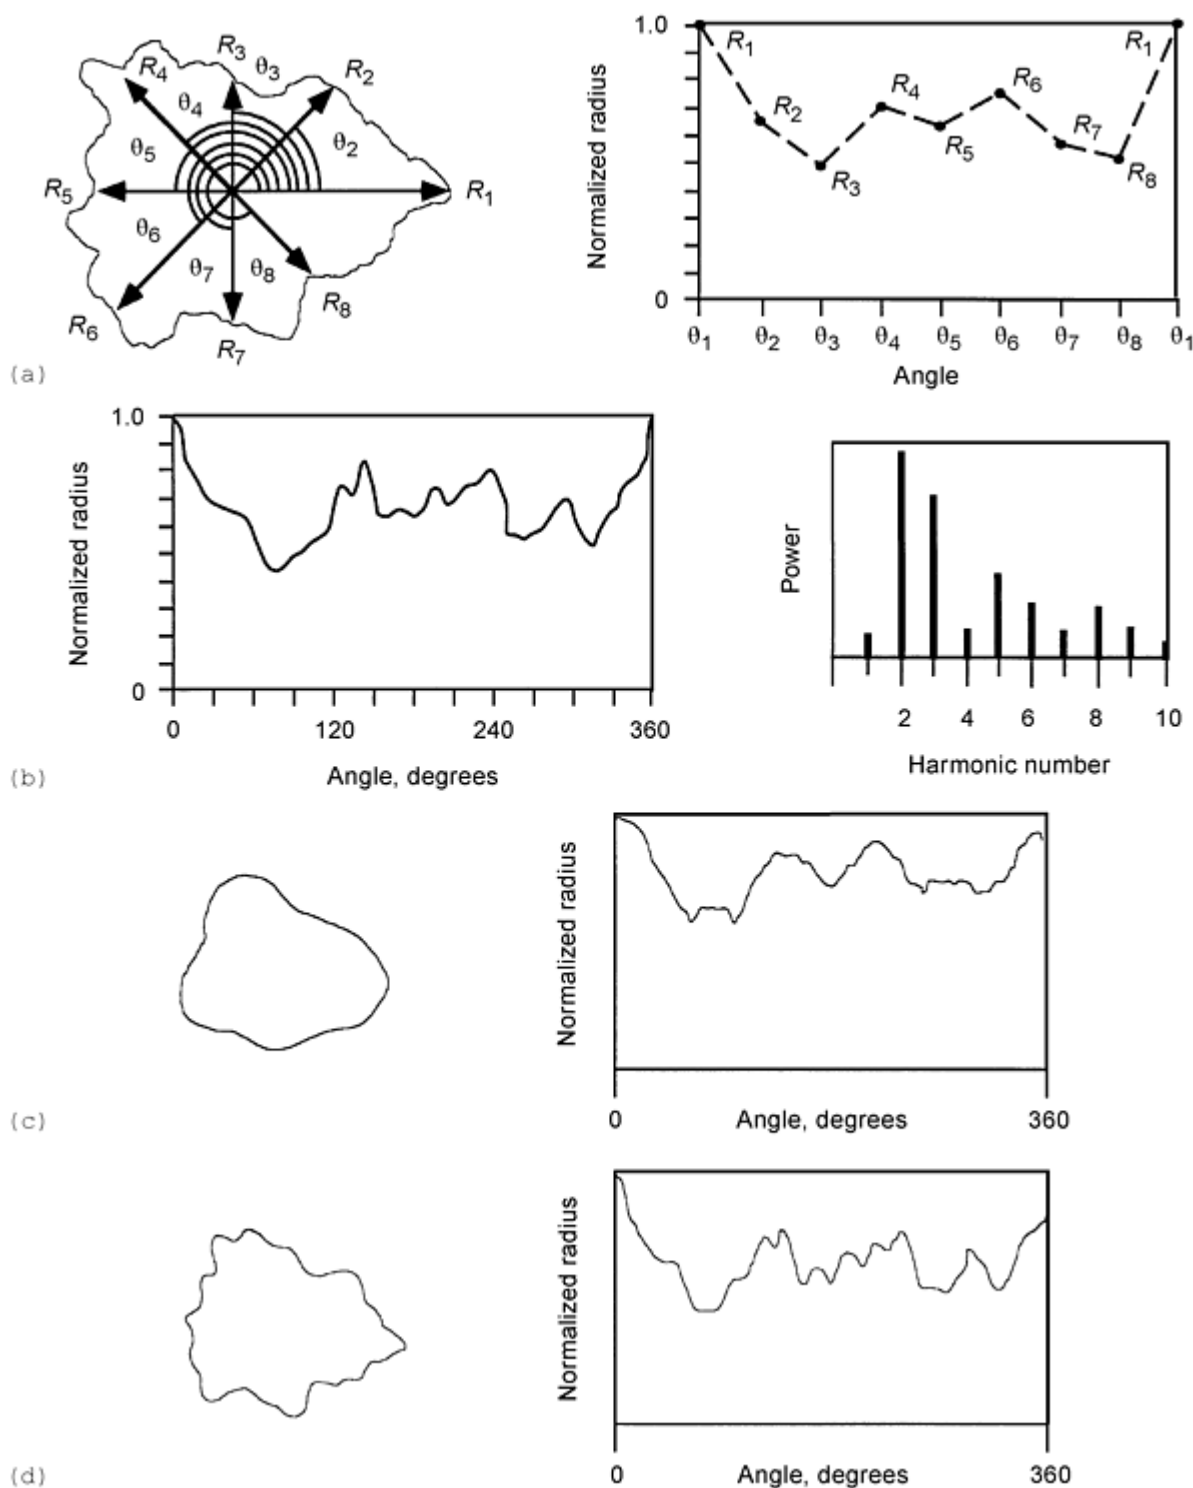

Fig. 16 Geometric signature waveform of a profile subjected to Fourier analysis to extract information on structure and texture. (a) Method used to obtain a simple geometric signature waveform. (b) More detailed signature waveform for the profile of (a) along with its harmonic spectrum. (c) First 5 harmonics used to reconstruct the profile show the gross morphology of the profile. (d) First 25 harmonics used to reconstruct the profile and add textural information to the structure

Fractal Analysis. Another technique for characterizing the texture for a metal profile is to measure the fractal dimension. Again current techniques available for measuring the fractal dimension are restricted to the use of two-dimensional images. The concept of a fractal dimension for measuring the ruggedness of a boundary was pioneered by Mandelbrot (Ref 17). Mandelbrot proposed that one way of describing the ruggedness of a boundary in space is to add a fractional number to the topological dimension of the system being studied to describe space-filling ability. In the

description of the boundaries of powder grains, the topological dimension of a boundary in a two-dimensional space is one. Figure 17(a) shows basic concepts of systems put forward by Mandelbrot. There are several ways to characterize the fractal dimension of the profiles; one convenient technique is to explore the perimeter structure of various inspection resolutions and to construct a Richardson plot of the data generated.

(a)

(b)

Fig. 17 Properties of the mathematical construction known as the Koch Triadic Island (a) Construction algorithm of the Koch Triadic Island. Each straight-line segment is divided by three, and the center segment is replaced with two segments of the same length at 60° to each other. (b) Triadic Island illustrating the property of self similarity. The magnification of an image of a boundary cannot be known because it looks the same at any magnification.

The physical significance of these statements can be appreciated from the diagram summarized in Fig. 18. The first step in the evaluation of the fractal dimension of a profile is to digitize the profile as shown. A polygon from the perimeter of the profile is then constructed by counting off a number of steps around the profile. A polygon constructed in this way is an estimate of the perimeter at the resolution fixed by the number of steps taken around the perimeter. It can be shown that for an irregular perimeter that can be described by a fractal number, the plot of the estimates of the perimeter versus the size of the inspection stride (the term used to describe the step created by going a certain number of steps around the profile) on log-log graph paper generates a linear-data relationship. Furthermore, the absolute value of the slope is the fractional number to be used in the fractal dimension of the profile. This plot is known as the Richardson plot, named in honor of a pioneer scientist who studied the structure of irregular boundaries. Figure 18(b) and 18(c) show such a series of measurements and the data plot. A very rugged profile can have more than one data line on the graph. For example, in the case of powder formed by a fuming process such as a carbon black, a profile such as that of Fig. 19 can have two different data lines on the Richardson plot. The data line at high resolution represents the texture of the profile, whereas the data line of the coarser resolution is a measure of the overall gross structure of the profile. Figure 20 shows the shape, size, and fractal dimension of the population of powder grains from Fig. 10(a). Again the change of values of the three parameters can be quantified by treating the points representing the information as unit masses in space. This type of graph is used to look at the range of shapes in an abrasive powder.

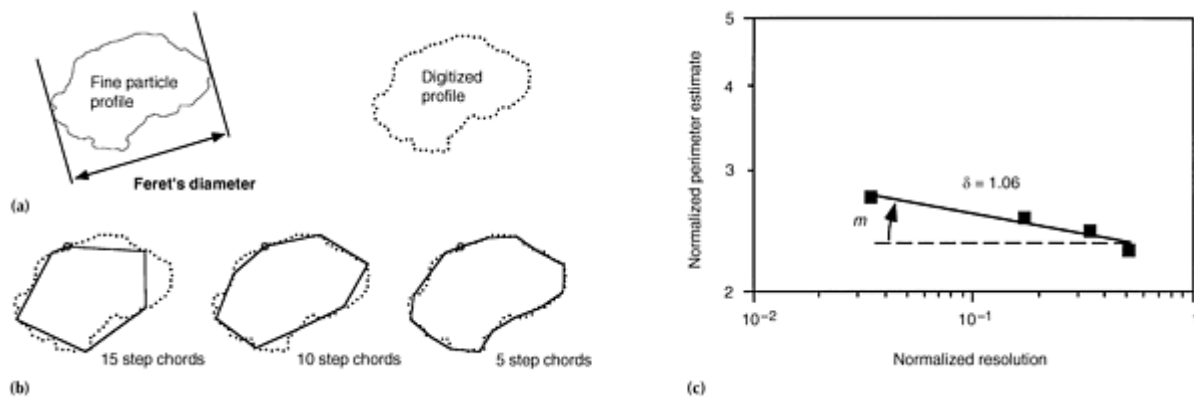

Fig. 18 Boundary fractal dimension of a profile--a dimensionless descriptor of the ruggedness of a fine particle boundary. (a) First step of the equipaced method of determining the boundary fractal. Profile is converted to a series of equally spaced (x,y) coordinates. (b) Estimates of the perimeter of the profile made at a series of decreasing step sizes. (c) Data normalized by dividing by the Feter's diameter and plotting perimeter estimate versus resolution of inspection on log-log graph paper. Fractal dimension (δ) = 1 + |m| where m is the slope of the best fit line through the data.

Fig. 19 Structural boundary fractal dimension (δ_s) relates to the gross morphology of the fine particle. Textural boundary fractal (δ_T) relates to the smaller features of the profile.

Fig. 20 Individual powder grain of Fig. 10(a) characterized by its fractal dimension and combined with size and chunkiness to form a single point in three-dimensional space. When a group of powder grains are treated in this way, they produce a cloud of points characteristic of the powder.

Particle Image Analysis

Particle Shape Factors*

The most common approach to describe and differentiate particle shapes has been the use of qualitative concepts. Two fundamental concepts have been used: (a) the dimensionality of the particle and (b) the surface contour of the particle. By the use of these concepts, a model system of shape characterization is presented in Fig. 21. Photomicrographs of several types of loose powders described in the International Standards Organization standard ISO 3252 are shown in Fig. 22. Basic shapes are:

- *One-dimensional particles* (Fig. 22a and 22d). Two different types of one-dimensional particles can be considered on the basis of their surface contour. One particle is smooth and the other particle is roughened with an irregular type of surface.
- *Two-dimensional particles*. These are very flat in nature and the surface contour of such particles is usually irregular. The dendritic type (Fig. 22c) is characterized by a tree-like shape and is often associated with electrolytic powders. However, secondary mechanical treatments often destroy such a shape. Flake particles (Fig. 22e) are also considered two-dimensional particles.
- *Three-dimensional particles*. Most powders are three dimensional in nature. These powders can be equiaxed and nodular. The simplest type of particle in this category is the spherical type (Fig. 22i). By departing from this perfect shape and contour, irregular particles (Fig. 22g) and nodular types (Fig. 22h) are obtained.

Fig. 21 Various shapes of powder particles and their methods of manufacture

Fig. 22 Common particle shapes as depicted in ISO 3252. (a) Acicular powder particles. (b) Angular powder particles. (c) Dendritic powder particles. (d) Fibrous powder particles. (e) Flaky powder particles. (f) Granular powder particles. (g) Irregular powder particles. (h) Nodular powder particles. (j) Spheroidal powder particles

Porous particles are different from irregular particles because of the presence of porosity, which can also be very irregular in both size and shape. Internal porosity may be isolated or interconnected. Large amounts of porosity make shape characterization difficult. It is best observed by examination of cross sections of mounted powder.

Particle Image Analysis

Electron Microscopy

Qualitative SEM Shape Analysis. The most significant feature of the scanning electron microscope, in addition to its high magnification capability (useful magnifications beyond 10,000 \times), is its ability to produce images with a three-dimensional appearance. This ability derives from the fact that the depth of field for the scanning electron microscope is over 100 \times that of the optical microscope. This increased depth of field (ranging from 1 μ m at 10,000 \times to 2 mm at 10 \times) also accounts for the extensive particulate analysis performed on the scanning electron microscope at magnifications that are within the capabilities of optical microscopy.

The imaging capabilities of the scanning electron microscope make it a useful tool for P/M applications concerned with all phases of powder production and processing. Scanning electron microscopy has been used to study all aspects of

particle morphology, including size, shape, surface topography, surface structure (crystal, grain, and dendrite), coating or thin film characteristics (oxides), inclusion, void, and agglomeration characteristics, and satellite formation. The scanning electron microscope has also been used to study surface topography, effect of oxides or other coatings, porosity, inclusions, and other contaminants on P/M materials.

One of the more useful applications of the scanning electron microscope in powder metallurgy is qualitative particle characterization in terms of visual appearance. Despite the development of automated instruments for quantitative particle characterization, no substitute has been found for the interpretive capability of man. The use of the scanning electron microscope extends this capability into the microscopic domain.

Inspection of powder particles to be used in P/M processing is essential, because individual and agglomerate characteristics can have significant effects on final material properties. Figure 23 shows representative alloy powder particles used in the direct rolling of aluminum P/M strip. The irregular shape promotes interlocking of particles, which provides sufficient green strength for strip processing.

Fig. 23 Scanning electron micrographs of 7091 aluminum alloy particles used in direct powder rolling of strip. (a) 70 \times . (b) 700 \times

Quantitative Analysis of Projected Images. In general, microscopists encounter two types of projected images. The first type of image results from a transmitted beam through the specimen, representing the features located within the three-dimensional space (such as by thin-foil transmission electron microscopy). In the second type, the projected image is generated by a reflected beam from the external surface of the specimen (such as by scanning electron microscopy).

Only the most rudimentary quantitative calculations can be made on images projected by the reflection techniques (Ref 18). In rough surfaces, the intensity levels depend on topography, and some features may be masked by others. Three-dimensional characterization is based on the photogrammetric analysis of stereopairs, for which automatic image-analyzing techniques are not yet available (Ref 19).

Quantitative statistical treatment of transmitted-beam images, however, has matured to a much greater extent. These analyses (Ref 20, 21) are too lengthy and complex to be treated here, but are described in the literature (see Ref 5).

One final topic will be included, because of its importance to the analysis of particulate systems. Figure 24 provides interrelated general equations of convex particles that express the important spatial parameters in terms of measurements made on the polish and projection planes. Application of the equations to specific particles is summarized in Table 2 for the sphere, the truncated octahedron (or tetrakaidecahedron), and convex particles in general. Tabulations of the type presented in Table 2 permit the microscopist to approximate microstructures with particles of known shape when other techniques are not feasible.

Table 2 Properties of a sphere, truncated octahedron, and convex particles

Property	Sphere, $D = 2r$	Truncated octahedron, edge length = a	General equations for convex particles
V	$4\pi r^3/3$	$11.314a^3$	$V = A'L_3 = AH'$
S	$4\pi r^2$	$26.785a^2$	$S = 4A' = 4V/L_3$
A'	πr^2	$6.696a^2$	$A' = S/4 = V/L_3$
H'	$2r$	$3.0a$	$H' = V/A = A'L_3/A$
A	$2\pi r^2/3$	$3.77a^2$	$A = V/H' = A'L_3/H'$
L_3	$4r/3$	$1.69a$	$L_3 = 4V/S = AN_A/N_L$
$r, a, \rho^{(a)}$	$r = 2N_L/\pi N_A$	$a = 0.45N_L/N_A$	$\rho = H'/2 = N_A A / 2N_L = A'/2L_2$
N_v	$\pi N_A^2 / 4N_L$	$0.744 N_A^2 / N_L$	$N_v = N_A / H' = N_L / A'$
General equation: $V_v = N_v V + N_A A = N_L L_3$

Particle Image Analysis

Conventional Shape Factors

Particle shape is a fundamental characteristic of powder particles and thus influences the properties of particulate systems. Various shape terms have been proposed to quantitatively represent particle shape. Early systems tended to measure one specific feature of a particle.

Table 3 (Ref 23, 24, 25, 26, 27, 28, 29, 30) lists some of the most frequently used shape terms. The applicability and/or limitations of various shape factors, also referred to as shape parameters, are discussed in the following section of this article on stereological characterization of shape. For discussion purposes, the following method developed by Hausner (Ref 28) is used to demonstrate the applicability of shape factors in quantitative analysis of particle shape.

Table 3 Shape terms and their definitions

Volume specific surface (S_v)	
$S_v = S/V$	V : Particle volume S : Particle surface area
Heywood ratios (Ref 24)	
Elongation ratio (n) $n = L_h/B_h$	B_h : Breadth--the minimum distance between two parallel planes that are perpendicular to planes defining T_h
Flakiness ratio (m) $m = B_h/T_h$	T_h : Thickness--minimum distance between two parallel planes tangential to the particle maximum stability plane
	L_h : Length--distance between two parallel planes that are perpendicular to both T_h and B_h planes
Heywood shape factor (ϕ_h) (Ref 25)	
$\phi_h = f/k$ where $f = S/d_a^3$ $k = V/d_a^3$	d_a : Diameter of a circle having the same projected area S : Particle surface area V : Particle volume For spheres: $n = m = 1$, $\phi_h = 6$
Wadell	
Sphericity (ψ_s) (Ref 26) $\psi_s = (d_v/d_s)^2$ $\approx 4.84 (k/f)^{2/3}$	d_v : Diameter of the sphere that has the same volume of the particle f, k : Diameter of the sphere having the same surface area as the particle (defined in Heywood ratios)
Roundness (ψ_r) (Ref 27) $\psi_r = \frac{\sum_{i=1}^N r_i}{NR}$	r_i : i th radius of curvature along the particle profile which is smaller than the radius of the largest inscribed circle N : Total number of radii of curvature smaller than the inscribed circle R : Radius of the largest inscribed circle
Krumbein (Ref 28)	
Sphericity (ψ_k) $\psi_k = 3\sqrt{\left(\frac{T_k}{B_k}\right)\left(\frac{B_k}{L_k}\right)^2}$	L_k : Longest dimension of the particle B_k : Breadth--measured perpendicular to L T_k : Particle thickness
Hausner (Ref 29)	
Elongation ratio (x) $x = a/b$	a : Length of the enveloping rectangle that has the minimum area b : Width of the rectangle
Bulkiness factor (y) $y = A/ab$	A : Projected area of the particle c : Perimeter of the projected profile
Surface factor (z) $z = c^2/12.6A$	
Church shape factor (ϕ_c) (Ref 30)	
$\phi_c = E(d_M)/E(d_F)$	d_M : Martin's diameter--length of the chord which divides the profile into two equal areas with respect to a fixed direction $E(d_M)$: Expectation of Martin's diameter d_F : Feret's diameter, the distance between a pair of parallel tangents of the particle profile with respect to a fixed direction $E(d_F)$: Expectation of Feret's diameter
Centroid aspect ratio (CAR) (Ref 31)	
CAR $= d_m/d_p$	d_m : Longest chord passing through the centroid

A rectangle of minimum area is drawn around the cross section of a particle (particle projection) as it is observed under the microscope (Fig. 25). The ratio of the rectangle side lengths permits calculation of particle elongation:

$$\text{Elongation factor, } x = \frac{a}{b}$$

Fig. 25 Determination of particle size characterization. (a) Length of the enveloping rectangle, which has a minimum area. (b) Width of the rectangle. (c) Circumference of the projected particle. A , surface area of the projected particle

The ratio of the area (A) of the projected particle to the area of the enveloping rectangle of minimum area ($a \times b$) indicates the bulkiness of the particle:

$$\text{Bulkiness factor, } y = \frac{A}{a \times b}$$

In this way, the cross-sectional area of the particle is correlated with some of its linear dimensions.

To characterize the surface configuration (or surface area), which is an essential factor of shape, the surface of the respective particle should be compared with the surface of a sphere of identical volume, or a cross section should be compared with that of the particle:

$$\text{Surface factor, } z = \frac{c^2}{12.6A}$$

where c is the perimeter of the projection profile of the particles. For a spherical particle, $z = 1$, and for particles of any other shape, $z > 1$.

Although the three ratios (x , y , and z) do not permit exact characterization of particle shape, they are nevertheless descriptive. It is possible, therefore, to correlate particle behavior with the three ratios--elongation factor, bulkiness factor, and surface factor. As indicated, however, there have been other shape factors proposed to characterize particle shape (see Table 3 and the next section of this article).

Particle Image Analysis

Stereological Characterization

Stereology refers to the study of the three-dimensional structure of materials from two-dimensional sections or projections. This discipline is primarily concerned with the geometrical evaluation of microstructural features, based primarily on geometrical probabilities. However, statistics, topology, and projection geometry also contribute to the overall quantitative characterization (Ref 20, 31). Quantitative characterization of the shape of microstructural features (e.g., pore space, precipitates, phase regions, and grains) and of particles on a substrate or embedded in a resin by means of data derived from planar images (sections or projections) is the prime consideration of stereology.

Stereology usually does not apply to the geometric nature of single particles, but rather to the geometric characteristics of a large number of particles or to the geometric characteristics of the "average particle" in a powder mass. Detailed information on the fundamentals, instrumentation, and applications of quantitative stereology can be found in Ref 18, 19, 20, 21, 22, 32, and 33.

Numerous shape parameters have been proposed, but only a few are practical. A useful stereological shape parameter (factor) must fulfill several requirements:

- *Shape sensitivity*: The value of a particular parameter must vary systematically with changes in shape--it should be sensitive to specific aspects such as elongation, bulkiness, and symmetry.
- *Independence of other geometric properties*: Size, size distribution, volume fraction, or other non-shape-related geometric characteristics should not influence the value for a given shape parameter.
- *Accessibility*: Quantities from which a stereological shape parameter is calculated must be available by simple measurements performed on planar images.

Other less significant requirements are that shape parameters must be dimensionless and independent of rotation or translation of the objects. Furthermore, it should be easy to visualize the significance of a shape parameter in terms of interpretable microstructural shape changes. The range for typical microstructural changes should be wide compared to statistical fluctuations and measuring errors.

From the parameters listed in standard textbooks (Ref 22, 32) and from parameters proposed in literature (Ref 34, 35, 36, 37), none conforms to these requirements completely. In the following sections, some of the more useful stereological shape parameters, their limitations, and their practical alternatives (fingerprinting by means of simple two-dimensional parameters) are discussed.

Image Data for Shape Characterization

With manual or semiautomatic data acquisition (in which counting and measurements are performed by the operator), only average quantities for the measured fields of view (field quantities), such as area fraction, total and mean intercept length, total and mean perimeter length, mean curvature, and number of features per unit area or unit length, can be obtained in a timely manner. Automatic instruments facilitate measurement of parameters describing the geometric

properties of each individual planar feature, as seen in the fields of view at a high speed. From those parameters that can be used for shape description, the following have been shown to be of practical use: individual intersect areas, intercept length, tangent (Feret) diameters, as a function of direction and their extreme (maximum and minimum) for each closed planar feature; individual curvature; and moments of inertia.

Concise characterization of three-dimensional shape is possible only if the spatial coordinates of the particle surfaces or three-dimensional feature parameters (spatial Feret diameters, spatial moments of inertia, surface areas, and volumes of the particles) are available. Direct acquisition of three-dimensional data is possible by (a) serial sectioning, (b) stereometric measurements using SEM stereo-pair photographs and instrumented stereometers, and (c) additional specialized techniques, including x-ray topography, shadowgraphy, or densitometry (for semi-transparent materials). However, these techniques are time consuming and not yet well established.

Stereology of Shape

It is generally agreed that three-dimensional shape cannot be quantitatively assessed from planar images without severe limitations. For example, topological parameters, such as the number of separate parts (e.g., the number of pores in a porous particle) or the degree of connectivity (the number of channels between the pores), cannot be obtained from a single cross section. From projections, especially from stereo-pair micrographs, a qualitative shape description can be easily derived. For stereological quantification, however, the data obtained from projections are generally less suitable than those obtained from the cross sections of particles embedded in a resin, a metal, or in a glass prepared by normal metallographic techniques.

Thorough analysis of stereological shape parameters obtained from a single cross section through a multitude of particles was proposed in the literature (Ref 38), intended to show that parameters that depend exclusively on the shape of the three-dimensional objects, and not on size or other non-shape-related features, can be traced to one simple combination of field data. This combination is the number of intersecting points between a measuring line and the perimeters of the particle cross section (P_L), which for convex particle features, is twice the number of particles per unit length of the measuring traverse-- N_L ($P_L = 2N_L$)--the volume fraction (V_V) measured as area fraction (lineal fraction or point fraction) and the number of objects per unit area (N_A). Fischmeister (Ref 38) derives the universal shape parameter:

$$F_F = \frac{1}{6\pi} \cdot \frac{N_L^2}{V_V \cdot N_A} \quad (\text{Eq 1})$$

The numerical factor aims to normalize the value to 1 for spheres. However, it can be easily demonstrated that this shape parameter is not independent of the size distribution, and deviations from a value of 1 for spheres of varying size are possible. A shape parameter that is actually independent of other geometric properties was proposed by De Hoff (Ref 39) in 1964:

$$F_D = \frac{1}{6\pi} \cdot \frac{N_L^2}{V_V \cdot N_A} \cdot \frac{M_1 \cdot M_3}{M_2^2} \quad (\text{Eq 2})$$

where M_1 , M_2 , and M_3 are the first three moments of the spatial size distribution, which generally are not accessible from planar data without a priori information on shape (the shape of the particles must be simple and known in order to calculate three-dimensional size distributions from planar measurements). F_D reduces to F_F for uniform size, while logarithmic-normal size distributions with known standard deviation $\ln \sigma$ yields:

$$F_D = \frac{1}{6\pi} \cdot \frac{N_L^2}{V_V \cdot N_A} \exp (\ln \sigma)^2 \quad (\text{Eq 3})$$

The only other parameter that appears to meet the three basic requirements outlined above has been derived by Hilliard (Ref 40) from a geometric theorem relating the total surface and the total volume of three-dimensional objects to the first and the fourth moment of the intercept length distribution-- $M_1(1)$ and $M_4(1)$ (see Ref 34). After normalizing to 1 for spheres again, this yields the shape parameter:

$$F_H = \frac{2}{3} \frac{N_L^2}{V_V} \sqrt{\frac{2}{3} M_4(1)} \quad (\text{Eq 4})$$

N_L and V_V are defined above. The main limitation of F_H is that it fulfills Eq 3 in principle only; in practice, $M_4(1)$ is subject to large experimental errors due to the fact that the longest intercepts, which usually are present with a low numerical frequency, contribute most to $M_4(1)$.

Numerous other shape parameters have been proposed by Underwood (Ref 35, 36), Ministr (Ref 41), and others. However, most equations are in pronounced contradiction to one or more of the basic requirements for true shape factors. Due to the problems outlined in this section, two-dimensional shape characteristics provide practical alternatives and as such are used almost exclusively in practical work.

Quantitative Description of Planar Shape

Two-dimensional shape parameters provide a means to monitor shape changes occurring in microstructures of P/M products due to variations in processing parameters and a means to compare the particle shape of powders obtained with different materials and production techniques. For this method, Fischmeister (Ref 39) uses the term "fingerprinting," because if applied properly, it yields indirect but accurate information on three-dimensional shape. The basic requirement outlined previously, however, must also be observed for two-dimensional shape factors.

Hausner's shape parameters, described earlier in this article in the section on conventional shape parameters, are an example of "fingerprinting," as are other methods of planar shape description, such as Fourier coefficients and fractals of the sectioned or projected particle circumferences. In sectioned or projected particle circumferences, parameters are described that are sensitive to particular shape aspects and are easily determined with semiautomatic or fully automatic image analyzers. In the Hausner method, the fitting of the minimum area rectangle requires repeated fitting, which in some cases leads to ambiguous results.

By far the most frequently used planar shape parameter (implemented in most image analyzing devices) combines the area and the perimeter of a planar feature into a dimensionless number normalized to 1 for circles of the same size:

$$f_{PL} = 4\pi a/b^2 \quad (\text{Eq 5})$$

where a and b are the area and the perimeter of the planar features (intersects or projections), respectively. Averaging can be completed easily if a and b are measured individually for each feature:

$$\begin{aligned} F_L &= \sum_{i=1}^n f_{PL} / n \\ &= 4\pi \sum_{i=1}^N (a/b^2) / n \end{aligned} \quad (\text{Eq 6})$$

where n is the total number of planar features. However, if a and b are averaged, or if total area and perimeter length are used (as provided by field analysis), the average shape parameters obtained depend on size distribution, with values deviating from unity for a system of circles of varying diameter.

If Eq 6 is used, deviations from unity are interpreted as deviations from circularity. Elongation (elliptical deformation), as well as concave deformations of the perimeter ("rugged" outlines), yields smaller values approaching zero for highly elongated features or highly rugged perimeters.

Thus, F_L combines different aspects of shape. To differentiate between these aspects, simple combinations of moments of inertia, Feret diameters, or curvature have been derived by Schwarz (Ref 42). Exner and Hougardy (Ref 34) propose the following parameters for individual features, which also can be averaged for any number of features in the same way as f_{PL} (see Eq 6):

$$\text{Elongation, } f_{EL} = \sqrt{i_1/i_2} \quad (\text{Eq 7})$$

$$\text{Compactness, } f_{COM} = \frac{1}{2\pi} \cdot \frac{a^2}{\sqrt{i_1^2 + i_2^2}} \quad (\text{Eq 8})$$

$$\text{Ruggedness (waviness), } f_{RU} = b_c/b \quad (\text{Eq 9})$$

where i_1 and i_2 are the two principal moments of inertia, b_c is the convex perimeter, and b is the actual perimeter.

These parameters are sensitive to the respective shape aspects, are easily measured by computer-aided image analysis, and are independent of other geometric properties; their interpretation through visualization is easily accomplished.

Consideration should be given to the method of averaging, however. Averaging on a volume basis, rather than on a number basis as in Eq 6, may be appropriate in some practical applications. If three-dimensional measurements are performed, similar shape parameters can be derived for the various aspects of spatial shape.

Multidimensional Shape Characterization

In order to analyze differences in shape precisely, more than one shape aspect must be monitored. Depending on the number of aspects considered using mutually independent shape parameters, two-, three-, or multidimensional representation of shape can be useful for comparison, and cluster analysis may be appropriate to quantify the significance of differences. Figure 26 shows a two-dimensional shape characterization of idealized particles in a ruggedness/elongation diagram.

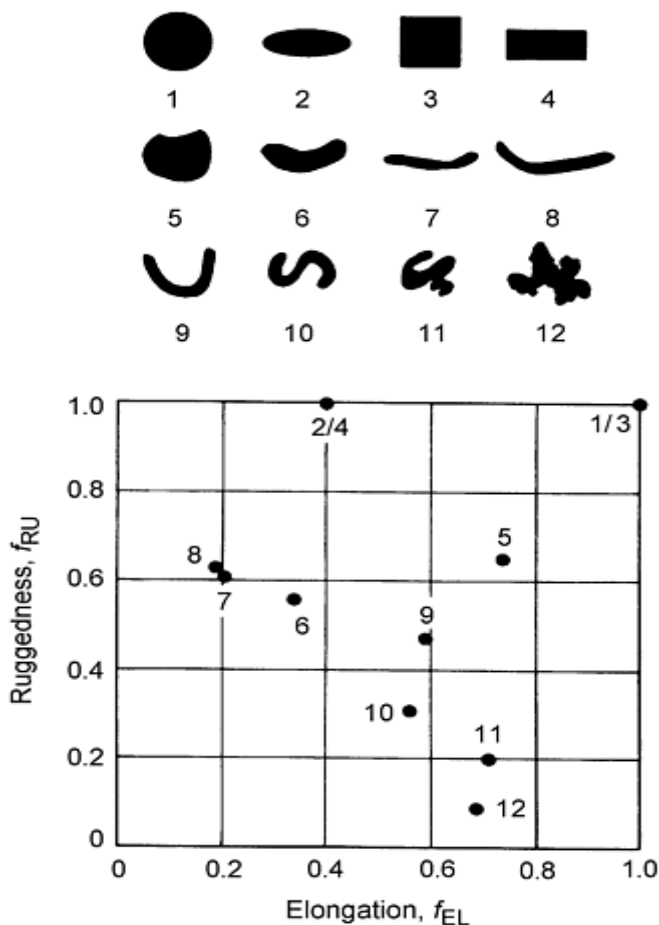

Fig. 26 Characterization of the shape of twelve typical particle projections (or sections) in a two-dimensional shape space

These procedures require a computer with a large capacity, but which is modest compared to Fourier analysis, for example. The assessment of the individual parameters involves straightforward arithmetic calculation, and cluster analysis is performed on a few numbers for each feature measured.

Simple shape characterization, normally accomplished using Eq 6, prevails in practice, because the multidimensional procedures referred to previously are not yet implemented in commercial image analyzers. At present, the best approach to the difficult problem of quantitatively characterizing the shape of a system of particles in a powder mass is to use one or several shape parameters carefully adjusted to the problem under investigation.

Particle Image Analysis

Morphological Analysis

Morphological analysis is primarily the characterization of particle shape. Particle size may also be obtained in the analysis (Ref 30). Typically, a shape analyzer is used to conduct the analysis. This instrument, which consists of a high-quality imaging (graphics) system that is augmented with computer equipment, must provide a clear image of the object for effective and accurate morphological analysis.

The image is digitized to obtain the (x, y) data set of the profile. This data set is then converted to the polar form. The polar data set (R, θ) constitutes a line, and the Fourier equation that represents this line can be constructed and the set of coefficients extracted from this equation. In turn, the coefficients are converted to invariant forms called "morphologic features." Statistical properties of these features are also determined.

The rigorous definition of various morphological descriptors are given in Eq 10, 11, 12, 13, and 14, and statistical properties are given in Eq 15, 16, and 17. The size term is defined as the equivalent radius, R_0 , of the particle profile, such that R_0^2 is the area of the circle of equivalent area to that of the particle profile.

$$R_0 = \sqrt{a_0^2 + \frac{1}{2} \sum_{n=1}^{\infty} (a_n^2 + b_n^2)} \quad (\text{Eq 10})$$

The mean radius a_0 and R_0 are related as follows:

$$L_0 = \frac{a_0}{R_0} \quad (\text{Eq 11})$$

$$L_1(n) = 0 \text{ for all } n \quad (\text{Eq 12})$$

The next set of terms, called the $L_2(n)$ terms, where n is the order of the Fourier coefficient, is useful in describing morphologic features such as aspect ratio, triangularity, squareness, roughness, and other shape aspects.

$$L_2(n) = \frac{1}{2R_0^2} (a_n^2 + b_n^2) \quad (\text{Eq 13})$$

($n = 1, 2, 3, \dots$ N is the order of the coefficient)

$$L_3(m, n) = \frac{3}{4R_0^3} (a_m a_n a_{n+m} - b_m b_n a_{n+m} + a_m b_n b_{n+m} + b_m a_n b_{n+m}) \quad (\text{Eq 14})$$

The mean, standard deviation, and skewness of the radial distribution of the particle are defined below. They are standard statistical properties and each has a distinct physical meaning. For example, the standard deviation is an indicator of the not-roundness of the particle profile.

$$\mu_0 = L_0 R_0 \text{ (mean radius)} \quad (\text{Eq 15})$$

$$\mu_2 = R_0^2 \sum_{n=1}^{\infty} L_2(n) \quad (\text{Eq 16})$$

(second moment about the mean)

$$\mu_3 = R_0^3 \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} L_3(m, n) \quad (\text{Eq 17})$$

(third moment about the mean)

Morphological Descriptors and Statistical Terms. Morphological descriptors are unique in that they can be used to regenerate the form of the original particle profile. A set of descriptors therefore, contains all of the information in the original profile. Because morphological analysis has been developed to solve real problems, it is important that the morphological features can be identified with a corresponding physical meaning wherever possible.

The equivalent radius R_0 is defined so that πR_0^2 is the area of the particle. Therefore, R_0 can be interpreted as a size term; a_0 is the mean radius of the particle.

The series of terms $L_2(n)$ are defined in terms of the Fourier coefficients a_n and b_n , and they are normalized by dividing by R_0^2 to make them independent of size. Therefore, $L_2(n)$ terms are the equivalent of the Fourier coefficients A_n . In terms of their physical meaning, an indication of the relative strength of the $L_2(3)$ term can be obtained by dividing the value of $L_2(3)$ by the sum of $L_2(n)$. This value provides an indication of the angularity (triangularity) of the particle.

There is a relationship between the $L_3(m, n)$ terms and the radial skewness as shown in Eq 17. Therefore, if all of the $L_3(m, n)$ terms are summed and multiplied by R_0^3 , the skewness of the radial distribution can be obtained. A pear-shaped drop or a teardrop shape, for example, would provide a high value of skewness. However, the physical meaning of the individual $L_3(m, n)$ terms is not understood at present.

The statistical properties of the morphological features defined in Eq 15 and 17 have been discussed above. The second moment of the radial distribution (the radiance), which is defined in Eq 16, is interpreted as indicating the not-roundness (out-of-roundness) of the particle profile.

The equivalent radius squared minus the mean radius squared is equal to the sum of all the $L_2(n)$ terms multiplied by R_0^2 . Equation 10, therefore, relates intrinsic and extrinsic properties of the particle profile quantitatively. In addition, the radiance (the sum of the $L_2(n)$ terms) can be equated to a difference between the square of the size minus the square of the mean radius.

This discussion indicates that there is a basis for the physical interpretation of the morphological features of a particle profile. The exception to this is the physical meaning of the $L_3(m, n)$ terms. This problem requires further study.

Surface Area, Density, and Porosity of Powders

Introduction

A LARGE NUMBER of industries deal with powders at some point during their processing procedures. The characterization of surface area, porosity, density, and particle size is of particular importance. Especially in the case of metal powders, those characteristics are important factors for understanding and controlling material properties and processing behavior. Knowledge about the surface area of the powder is helpful in understanding the sintering behavior, because the reduction of surface area is the essential driving force for the sintering process. Porosity and density are closely related, and they may influence, for example, the hardness of the material.

Different techniques can be used to determine these powder characteristics. The methods used to determine surface area, density, and porosity are not specific to metal powders: many have been developed for testing other materials in powder form. The major characterization techniques are summarized below. Expanded discussions of several test methods can be found in subsequent sections of this article, including testing parameters, specifications, and instrumentation. When these techniques are used, however, the results of each test method can vary from the results obtained by a different technique. This is only partly due to sample variations. Yet, each test method determines those properties in a very specific way. Pore size and even surface area are ambiguous parameters. For example, the size of an ideal cylindrical pore would be defined as the radius or diameter of this cylinder. However, real pores are hardly ideal cylinders. The odd-shaped geometry of pores makes it difficult to define the size of such a pore, and each measuring technique has its own way of looking at those pores and determining an average pore size of the sample. The pore size also depends on whether the actual void size or the entrance size or neck of the pore is of interest. The latter could be the restricting factor for transport processes. It is also impossible to clearly define the surface area. Depending on the "yardstick" of the observer, a sample may have a larger or smaller surface area. An optical microscope may not show cracks and pores in a sample, whereas the same sample can show a substantial surface roughness under the electron microscope or when analyzed by gas adsorption techniques. Correspondingly, the value of the calculated surface area will be different.

- *Gas adsorption method:* Determines the surface area of a powder sample by measuring the amount of gas adsorbed on the sample surface at low temperatures. The data are then used to calculate the monolayer capacity from which the surface area is calculated using the "known" size of the adsorbed molecules. Nitrogen at liquid nitrogen temperature is the most common gas used; krypton at liquid nitrogen temperature is used for samples with an area of less than 1 m². Gas adsorption can also be used to determine pore volume and pore size distribution ranging from one Angstrom to about 100 or 200 nm.
- *Permeametry:* Measures the resistance to fluid flow through a compacted powder bed. This information is used to determine related properties of a powder, such as pore size distribution, specific surface area, or the average particle size for a packed powder sample.
- *Pycnometry:* Determines density by measuring the difference between the specific and bulk volumes of a sample. This method is based on the displacement principle, using the powder as the solid body and helium, water, or mercury as the displaced medium. Pycnometry can be used to determine total pore volume or density. However, it does not provide quantification of the pore size or the pore size distribution.
- *Mercury porosimetry:* Measures the volume of mercury intruded into the pores of a powder sample as a function of the pressure applied to the mercury. This method gives pore size and distribution over a wide range: 0.3 mm to 3 nm depending on the capability (pressure range) of the apparatus used. The method is based on the nonwetting behavior of mercury toward most materials. However, certain metals, for example, gold or copper, can react with mercury, and before those samples are to be

analyzed specific precautions have to be taken.

Although surface area, density, and porosity of powder are interrelated, a given powder sample may require the use of several testing methods to provide a complete analysis of these characteristics, because each technique is more or less sensitive for a specific sample. A comprehensive treatment of each of the methods is given in this article.

Surface Area, Density, and Porosity of Powders

Gas Adsorption

H. Giesche, School of Ceramic Engineering and Sciences, Alfred University

The Brunauer-Emmett-Teller (BET) (Ref 1) method of measuring specific surface area is based on the determination of the amount of gas that is adsorbed on the surface of the sample. The specific surface area (m^2/g) determined by this method includes the external as well as internal (pores) surface area. The surface area of closed pores cannot be determined because the adsorbing gas molecules have no physical path to that surface.

Surface Area, Density, and Porosity of Powders

Theory of BET Method

The BET model is based on a kinetic model of the adsorption process that was described first by Langmuir in 1916 (Ref 2, 3). Langmuir regarded the solid surface as an array of adsorption sites, and a state of dynamic equilibrium was postulated in which the rate molecules arrive from the gas phase and condense on the bare sites is equal to the rate at which molecules evaporate from occupied sites. In 1938 Brunauer, Emmett, and Teller extended Langmuir's kinetic monolayer adsorption theory to a multilayer adsorption theory. The following relationship was derived to calculate the monolayer capacity, V_m :

$$\frac{V}{V_m} = \frac{C [1 - (n+1) (P/P_0)^n + n(P/P_0)^{n+1}]}{[(P_0/P) - 1] [1 + (C-1) (P/P_0) - C (P/P_0)^{n+1}]}$$

In the actual experiment the adsorbed amount of gas, V , is measured as a function of gas pressure, P . P_0 is the saturation pressure of the liquefied gas at the corresponding temperature of the adsorption measurement and the ratio P/P_0 is often referred to as the relative pressure. The parameters C and n are part of the BET theory. The parameter C is:

$$C = \frac{a_1 v_1}{a_2 v_2} \exp \left\{ \frac{q_1 - q_c}{RT} \right\} \approx \exp \left\{ \frac{q_1 - q_c}{RT} \right\}$$

The parameters a , v , q , R , and T are the activity coefficient, vibration frequency, heat of adsorption, gas constant, and temperature, respectively (Ref 4). The parameter C can be regarded simply as a measure of the additional or specific heat of adsorption in the first adsorbed layer (q_1) compared to the heat of condensation, q_c , which is assumed to be valid for the second and following adsorption layers. The parameter n corresponds to the maximum number of adsorbed layers on the surface. Only when pore sizes are very small is there a physical limitation of the number of layers and the factor, n , has to

be considered. Usually n is assumed to be infinite and the "standard" BET equation results, which can then be rearranged to yield a linear relation:

$$\frac{P}{V(P - P_0)} = \frac{1}{V_m C} + \frac{(C - 1) P}{V_m C P_0}$$

A plot of $P/[V(P - P_0)]$ versus P/P_0 generally gives a straight line in the relative pressure range from $P/P_0 = 0.06$ to 0.3 . From the slope and intercept of this line, the amount of gas adsorbed in a monomolecular layer (V_m) is determined as well as the value of C . By using the specific size of the adsorbing molecule, the total surface area of the sample can then be calculated. It should also be noted that the value of C is quite sensitive to errors in the measurement, and it can vary by 50% or more depending how accurately data points are taken and whether or not certain data points are omitted in the calculation. Frequently, C values for metal surfaces are quite large (>100 or 200); under those conditions, the intercept of the BET line can be taken as 0. The latter approach is used in the so-called single-point BET method, when the monolayer capacity, V_m , is directly calculated from one single data point using the following equation:

$$\frac{P}{V(P - P_0)} = \frac{(C - 1) P}{V_m C P_0} \approx \frac{P}{V_m P_0}$$

or $V_m = V(1 - P/P_0)$.

Different gases can be used for the surface area determination. The different experimental results can be compared if the size of the adsorbed gas molecules is known. Different values for the so-called cross-sectional area (size) of the adsorbate molecule have been reported in the literature. The following tables lists values as used by Davis, DeWitt, and Emmett (Ref 5):

Adsorbate gas and temperature, K	Size according to the density of the liquid, nm ²	Revised values recommended in Ref 5, nm ²
Nitrogen, 78	0.162	0.162
Krypton, 78	0.152	0.208
Krypton, 195	0.297	0.434
Butane, 273	0.321	0.469
Butane, 195	0.247	0.375
Freon-21 (CHCl₂F), 273	0.264	0.401

However, even with the use of such modified cross-sectional areas, anomalies between different samples could be diminished, but not completely eliminated, as shown in the data in Table 1 (Ref 5). The interpretation of surface area results also has to be carefully evaluated when the BET- C parameter is very large. A value of several hundred is a strong indication of either the presence of microporosity, adsorption on active sites at the surface, or even a chemisorption effect. As shown, very clean metal surfaces can produce extremely large C values and the adsorption of the gas molecules occurs in those cases in highly localized positions on the surface. As a result, the calculated surface area may not reflect the true area of the sample.

Table 1 Surface area determinations with different size values of the adsorbed gas

Adsorbate solid	Gas (Temperature, K)	Area per gram using liquid density values, m ² /g	Area per gram using revised values (see text), m ² /g	C-parameter
Glass spheres (7 μm)	N ₂ (78)	0.434	0.434	150
	Kr (78)	0.322	0.441	32
	C ₄ H ₁₀ (195)	0.333	0.489	7
	CHCl ₂ F (195)	0.315	0.479	106
Tungsten powder	N ₂ (78)	2.69	2.69	81
	Kr (78)	1.96	2.68	290
	C ₄ H ₁₀ (273)	1.67	2.43	26
	CHCl ₂ F (273)	1.73	2.62	21
Zinc oxide	N ₂ (78)	9.40	9.40	155
	Kr (78)	6.82	9.34	150
	C ₄ H ₁₀ (273)	6.93	10.1	52
	CHCl ₂ F (273)	6.63	10.1	215
Silver foil (geometrical area, 1.56 m²/g)	Kr (78)	1.56	2.14	19
	C ₄ H ₁₀ (195)	1.22	1.78	6
	CHCl ₂ F (195)	1.13	1.72	11
Monel ribbon (geometrical area 1.56 m²/g)	Kr (78)	0.456	0.622	13
	C ₄ H ₁₀ (195)	0.652	0.952	4
	CHCl ₂ F (195)	0.577	0.878	7

Source: Ref 5

Values of the BET-C parameter for krypton adsorption at a temperature of 77 K (Ref 4) for various solids are:

Material	C-parameter
Organic materials	10-70
Glass	20-80
Silica	25-75
Ferric oxide	30-75
Nickel oxide	70-120
Silica gel	80
Ferrites	60-200
Micas	100-130
Tungsten powder	215, 290
Carbon black	230
Nickel film, contaminated	400, 1000
Nickel film, clean	1200, 2300

Surface Area, Density, and Porosity of Powders

BET Apparatus

Figure 1 shows the adsorption apparatus originally developed by Emmett. Commercial instruments are now totally automated, and instead of the burette-type mechanism to measure the adsorbed gas volume very precise pressure transducers are used to calculate the adsorbed amount of gas from the known volume of a calibration chamber and the pressure drop that occurs when the valve between sample and calibration chamber is opened. Other instruments use a mass-flow controller to monitor the amount of gas introduced to the sample. In flow through cells, the adsorbing gas is passed over the sample using a carrier (helium, which is assumed to be nonadsorbing at the specific conditions). The composition of the gas stream before and after is analyzed to provide information about the total amount of adsorbed gas. A third technique uses a microbalance to measure the weight change as gases adsorb on the sample. Each technique has advantages and disadvantages. Further details are described in all standard textbooks (Ref 6, 7, 8, 9).

Fig. 1 Brunauer-Emmett-Teller apparatus for determining specific surface area

The isotherm is usually constructed point by point by the admission or withdrawal of known amounts of gas, with adequate time allowed for equilibration at each point. A small amount of heat is produced during the adsorption process, which has to be removed from the sample before final equilibrium is achieved. The amount of adsorbed gas is very sensitive to temperature changes. Prior to the determination of the isotherm all physisorbed material has to be removed. The exact conditions required to obtain a "clean" surface depend on the nature of the sample.

For the determination of the surface area and the mesopore size distribution by nitrogen adsorption, outgassing to a residual pressure of about 10^{-4} torr ($\approx 10^{-2}$ Pa) is considered acceptable. The outgassing conditions and the determination of the outgassed mass of the sample is one major source of error (or at least the reason for discrepancies between different experimenters). Inorganic oxides are usually outgassed at temperatures $\approx 150^\circ\text{C}$, while microporous carbons and zeolites require higher temperatures $\approx 300^\circ\text{C}$. Depending on the synthesis or other previous processing steps of the metals powders, the sample should be cleaned by washing with an appropriate solvent or treated at sufficiently high outgassing temperatures.

Usually nitrogen gas is adsorbed on the sample at liquid nitrogen temperature. The BET surface area determined from those measurements is used as a standard reference point. However, it might be appropriate or advantageous to use a different adsorbing gas in other applications. For example, nitrogen adsorption is limited to samples having a total surface area of more than 1 m^2 . However, small surface areas can be measured much more precisely by using krypton as the adsorptive gas. A total sample surface area of down to 50 cm^2 can be measured with many commercial instruments.

The increased sensitivity of the krypton analysis is due to the fact that the saturation pressure of krypton is only about 2.5 torr ($\approx 300\text{ Pa}$) at liquid nitrogen temperature. Due to this lower saturation pressure, the ratio between the actual amount

of adsorbed gas on the sample surface against the amount of gas that remains in the surrounding gas phase is much higher for krypton compared to the same data point in a nitrogen isotherm and correspondingly the amount of adsorbed krypton can be determined with a much higher precision. The next section demonstrates using a simple calculation why krypton measurements are so much more sensitive for low surface area samples.

However, krypton at liquid nitrogen temperature has other problems. The saturation pressure under those conditions cannot be unambiguously defined. According to the phase diagram (Fig. 2), krypton could either exist as a solid or as an undercooled liquid at that temperature. Most publications refer to the supercooled liquid state. This uncertainty severely limits the krypton analysis. A similar condition is also true for argon or xenon at liquid nitrogen temperature. In the case of argon, the experiment could be performed at a different temperature. For example, liquid oxygen would create a temperature of about 90 K, which is above the triple-point temperature of argon (83.8 K). However, liquid oxygen is much more problematic to handle and not as commonly available as liquid nitrogen.

Surface Area, Density, and Porosity of Powders

Krypton for Low Surface Area Determination

The use of krypton or argon rather than nitrogen for adsorbate improves the accuracy of low specific surface area measurements.

Assume the sample has a total surface area of 1 m² and the volume of the sample tube is 20 cm³. The saturation pressure for nitrogen is about $P_{0(N_2)} = 760$ torr and for krypton it is $P_{0(Kr)} = 2.5$ torr at liquid nitrogen temperature (assuming a super-cooled liquid state for the krypton).

The single-point BET equation for those gases yields:

$$V_m = 4.35 V_a (1 - P/P_0) \text{ for nitrogen}$$

and

$$V_m = 5.64 V_a (1 - P/P_0) \text{ for krypton}$$

At a relative pressure of $P/P_0 = 0.2$ the adsorbed volume, V_a , is then calculated to:

$$1.0 = 4.35 V_a (1 - 0.2)$$

or

$$V_a = 0.287 \text{ cm}^3 \text{ (STP nitrogen)}$$

$$1.0 = 5.64 V_a (1 - 0.2)$$

or

$$V_a = 0.222 \text{ cm}^3 \text{ (STP krypton)}$$

The remaining volume of gas in the sample cell can be calculated as follows:

$$20 \text{ cm}^3 \frac{(760 - 0.2) \text{ torr}}{760 \text{ torr}} \frac{273 \text{ K}}{77.2 \text{ K}} = 14.144 \text{ cm}^3 \text{ (STP for N}_2\text{)}$$

$$20 \text{ cm}^3 \frac{(2.5 - 0.2) \text{ torr}}{760 \text{ torr}} \frac{273 \text{ K}}{77.2 \text{ K}} = 0.046 \text{ cm}^3 \text{ (STP for Kr)}$$

As shown in Fig. 3, it becomes obvious that the ratio of adsorbed versus remaining gas allows for a much more accurate measurement in the krypton analysis.

Fig. 3 Ratio of adsorbed versus remaining gas demonstrates more accurate measurements in the krypton analysis compared to N_2 analysis for low surface area samples

Accuracy

The high degree of accuracy attainable in some branches of chemistry and physics is out of the question where evaluation of specific surface from adsorption data is concerned. Even in the favorable case of nitrogen or argon, a divergence of at least $\pm 10\%$ from the actual area of the solid should be expected (owing to theoretical factors not yet supported by accurate quantitative assessments). In addition, there are several nonnegligible experimental uncertainties, which can be strikingly illustrated by results of a round-robin test. The project embraced thirteen laboratories, all well experienced in the field (Ref 10). The participants determined detailed isotherms of nitrogen (often 30 to 40 points), calculating both the specific surface, based on $a_m(N_2) = 16.2 \text{ \AA}^2$ and the value of the BET C -parameter.

Solid	Surface area and standard deviation, m^2/g	No. of labs
Graphitized carbon (Vulcan 3G-2700)	71.3 ± 2.7	6
Graphitized carbon (Sterling FT-2700)	11.00 ± 0.8	5
Plasma produced silica (TK 800)	165.8 ± 2.1	4
Mesoporous silica gel (Gasil (1))	286.2 ± 3.5	3

Pore Size Analysis

Gas adsorption/desorption experiments can also be used to study the pore size distribution in a sample. Pores of up to 100 or 200 nm can be determined. The measurement is based on the capillary condensation effect, which essentially means that a gas will condense into a liquid phase below its saturation point when it is confined in small pores. The basic relationship between relative pressure and pore size is given by the Kelvin equation:

$$\ln\left(\frac{P}{P_0}\right) = -\frac{2\gamma_{lv}V_l}{RT r}$$

where γ_{lv} is the interfacial tension of the liquid-gas interface, V_l is the molar volume of the liquid gas phase, and the other factors are gas constant, R , temperature, T , and the radius of curvature of the liquid-gas interface, r . Numerous theories and models have been developed for the pore size analysis. The most commonly accepted theory was developed by Barrett, Joyner, and Halenda (Ref 11). Frequently, the adsorption-desorption isotherm shows a hysteresis and the shape as well as the relative pressure range where the hysteresis occurs provides information about the pore shape and pore size. Several theories have been developed to explain and analyze the hysteresis effect in more detail including deriving additional information about network and connectivity effects of the pore system in a sample. Details are described in several textbooks (Ref 6, 7, 8, 9).

Surface Area, Density, and Porosity of Powders

Permeametry

Peter J. Heinzer, Imperial Clevite Technology Center

Permeametry is the measurement of resistance to fluid flow through a compact powder bed. Its main purpose in powder metallurgy is not so much to quantify resistance as it is to measure the related properties of a particle population--namely, specific surface area and average particle size. Fluids may be in liquid or gaseous form. Liquid permeametry was prevalent in the early stages of development and is the simplest method if the minimum diameter of any appreciable size fraction is 5 μm (Ref 12). Settling and segregation, aggregation, and the difficulty of removing bubbles make liquid permeametry unsatisfactory for smaller-sized particles. Gas permeametry is now the preferred method because it extends the size measurement capability down to 0.1 to 0.5 μm .

Commercial permeametry is applicable in the following ranges (Ref 13, 14):

Specific surface area, cm^2/g ($\text{in.}^2/\text{g}$)	70-20,000 (10.8-3100)
Particle size, μm	0.5-50

In production practice, these ranges are subdivided into smaller segments to improve accuracy, because the behavior of fluid flow through powder beds with diverse characteristics changes considerably.

A typical sample occupies a volume of about 5 cm^3 (0.30 in.^3) and, depending on density, weighs from 5 to 20 g (0.18 to 0.70 oz). Reproducibility in the surface area range cited for commercial instruments is $\pm 1\%$. Accuracy varies with the type of sample, as discussed later in this section.

Inherent problems in the use of permeametry for particle size measurement involve its use of semiempirical relationships with parameters that can only be evaluated indirectly. Additionally, permeametric methods provide only an average particle size--not the more useful size distribution information. Despite these disadvantages, permeametry is popular due to its simplicity of operation, reproducibility, speed of analysis (2 to 15 min compared to 1 h or more with other methods), and low cost (one-fifth to one-tenth of the equipment cost of competing methods).

History and Theory

The original study of fluid flow through compacted particulate matter is attributed to D'Arcy (Ref 15), who examined water flow rates from the public fountains of Dijon, France, through sand beds of varying thicknesses in 1856. He formulated the basic principle behind permeability, showing that the average flow rate is proportional to the pressure gradient and inversely proportional to the thickness of the bed.

In 1927, Kozeny (Ref 16) published the first derivation showing correlation among porosity, permeability, and particle surface area. Following the lead of Blake (Ref 17), Kozeny treated the flow of fluid through a particulate bed as being equivalent to the flow of fluid through a comparable volume of parallel pipe channels of circular cross section. This simplification resulted in determining an equivalent diameter of pipe channel to characterize flow rate through the powder bed.

In 1938, Carman (Ref 18) and Dallavalle (Ref 19) independently proposed the determination of specific surface area for powders using permeability methods. Carman published related experimental work in 1941 (Ref 20). He developed a liquid flow technique to determine surface area for coarse materials by taking into consideration (1) the dependence of permeability on the number of permeable pores of the particle bed, (2) the pore or void volume fraction contribution to total bed volume, (3) the friction of the gas or liquid flowing through the bed, and (4) the adsorption of immobile liquid layers that effectively reduce the capillary diameter, thus causing less permeability and therefore a greater apparent surface area.

The Kozeny-Carman equation, given below, has served as the most widely used basis for all permeability variations:

$$S^2 = \frac{L^2}{2\eta v L_e^2 \rho^2} \frac{\Delta P}{L} \frac{f_v^2}{(1 - f_v)^3}$$

where S is surface area per unit weight of the powder, ΔP is the pressure drop across the powder bed, f_v is void fraction of packed sample, v is velocity of fluid flow, ρ is density of the powder material, η is viscosity of the fluid, L is length of the powder bed, and L_e is average path length through the powder bed.

Apparatus

Lea and Nurse (Ref 21) developed the apparatus shown in Fig. 4 to provide permeability measurements. The powder was compacted in the sample cell to a predetermined porosity. Air was permitted to flow through the bed, and the pressure drop (h_1) was measured on the first manometer; the air then passed through a capillary flowmeter, across which another pressure drop was measured as h_2 on a second manometer.

Fig. 4 Lea and Nurse permeability apparatus with manometer and flowmeter

The capillary permitted the system to operate under a constant pressure. The volume rate of flow through the flowmeter, the pressure drop across the bed as measured by the manometer, and the constants associated with the apparatus permitted determination of the specific surface area (surface area per unit volume).

Gooden and Smith (Ref 22) added a self-calculating chart to a modified Lea and Nurse apparatus to enable direct readout of the specific surface. The commercial version of their modification is known as the Fisher subsieve sizer (Fig. 5).

Fig. 5 Fisher subsieve sizer operation

A simplified version of the air permeameter, known as the Blaine permeameter (Fig. 6) (Ref 23), relied on a variable pressure technique (Ref 24). A vacuum was used to displace the oil in a U-tube connected in series with the powder cell. The resultant pressure caused air to flow through the powder bed, and the time required for the displaced oil to fall back to its equilibrium position was measured. This method resulted in a measured specific surface area, which decreased with porosity. Usui (Ref 25) showed that $\log t$ and the void fraction exhibited a linear relationship and that a plot of these parameters gave a value for surface area.

Surface Area, Density, and Porosity of Powders

Limitations

For very fine powders, the basic Kozeny-Carman equation is not accurate. This is because the laminar flow assumption on which it is based is no longer valid. Compressed fine particles result in a powder bed with very small channel widths. If these widths are comparable to the mean free path length of the gas molecules, laminar flow conditions are not maintained.

Such a situation, involving molecular flow or diffusion conditions, is known as Knudsen flow (Ref 26) and can occur with very fine powders or with coarser particles at low pressures. Figure 7 shows a typical apparatus used to measure fine particles under molecular flow conditions (Ref 27, 28). In some powders, both laminar and molecular flow may be significant. This is known as the transitional region.

Fig. 7 Modified Pechukas and Gage apparatus for fine powders. Source: Ref 27

Evaluating surface areas with steady-state flow conditions historically excluded noninterconnected blind pores. A method for including blind pores by utilizing transient-state flow measurements is the principle behind the apparatus shown in

Fig. 8(a) (Ref 29, 30). A typical flow rate curve, showing extrapolation of the steady-state portion to determine the time lag is given in Fig. 8(b). The basic principle of the permeability analysis has not changed much during the last several years; even so, instruments now use more sophisticated pressure transducer and flowmeter or flow controller. Combined with a computerization of the instrument and an improved data analysis software, the instrument offer a wider variety of analysis tasks and computational methods.

Surface Area, Density, and Porosity of Powders

Pycnometry

Peter J. Heinzer, Imperial Clevite Technology Center

Pycnometry is used to determine the true density of P/M materials. Based on the displacement principle, pycnometry is actually a method of determining the volume occupied by a solid of complex shape, such as a powder sample. For commercial pycnometers, typical sample sizes range from 5 to 135 cm³ (0.30 to 8.24 in.³). A properly prepared specimen can be analyzed in 15 to 20 min.

The pycnometric determination of density can be quite useful in P/M applications. In addition to its primary use in measuring the true density of a P/M part or product, it can be used to distinguish among different crystalline phases or grades of material, different alloys, compositions, or prior treatments.

Information on the porosity of a material can be obtained from pycnometry if the sample has a uniform geometry, or if the bulk volume is known. Pore volume is the difference between the bulk volume (1/bulk density) and the specific volume (1/true density). Finally, pycnometry can be useful in determining properties that relate to density. Often, P/M materials have no solid counterpart to use for measuring true density, making percentage of theoretical density measurements questionable. Pycnometric measurements of the true density of the powder have provided a good point of reference.

Density is one of the most important properties of P/M materials. Critical processing parameters, such as applied force and pressure, and properties of the resulting P/M product, such as strength and hardness, usually depend on the density of the materials being processed. Standard industry practice compares the achieved density of a P/M product with the full, or theoretical, density.

Surface Area, Density, and Porosity of Powders

Theory and Apparatus

Archimedes devised the first method for determining true density by using the displacement principle. Modern pycnometry represents a refinement of the displacement principle and uses either a liquid or gaseous substance as the displaced medium.

Absolute densities of solids can be measured by the displacement principle using either liquid or gas pycnometry. In liquid pycnometry, volume displacement is measured directly, as liquids are incompressible. Inability of the liquid to penetrate pores and crevices, chemical reaction or adsorption onto the sample surface, wetting or interfacial tension problems, and evaporation contribute to errors in density measurement. Therefore, gas pycnometry is usually preferred for P/M applications.

In gas pycnometry, volume displacement is not measured directly, but determined from the pressure/volume relationship of a gas under controlled conditions. Gas pycnometry requires the use of high-purity, dry, inert, nonadsorbing gases such as argon, neon, dry nitrogen, dry air, or helium. Of these, helium is recommended because it:

- Does not adsorb on most materials
- Can penetrate pores as small as 0.1 nm (1 Å)
- Behaves like an ideal gas

In commercial pycnometers, the sample is first conditioned or outgassed to remove contaminants that fill or occlude pores and crevices, thus changing surface characteristics. This is accomplished by evacuating the system and heating to elevated temperatures, following by purging with an inert gas such as helium.

The helium-filled sample system (Fig. 9) is "zeroed" by allowing it to reach ambient pressure and temperature. At this point, the sample cell and reference volume are isolated from each other and from the balance of the system by valves.

Fig. 9 Flow chart for typical pycnometer

The state of the system can then be defined by:

$$PV = nRT \quad (\text{Eq 1})$$

for the sample cell and:

$$PV_R = n_R RT \quad (\text{Eq 2})$$

for the calibrated reference cell. In these equations, P is the ambient pressure, Pa; V is the volume of the sealed empty sample cell, cm^3 ; V_R is volume of a carefully calibrated reference cell, cm^3 ; n is moles of gas in the sample cell volume at P ; n_R is moles of gas in the reference cell volume at P ; R is the gas constant; and T is ambient temperature, K.

A solid sample of volume (V_s) is then placed in the sample cell:

$$P(V - V_s) = n_1RT \quad (\text{Eq 3})$$

where n_1 is moles of gas occupying the remaining volume in sample cell at P . The system is then pressurized to P_2 , about 100 kPa (15 psi) above ambient:

$$P_2(V - V_s) = n_2RT \quad (\text{Eq 4})$$

where n_2 is moles of gas occupying the remaining volume in the sample cell at P_2 . The valve is then opened the connect the sample cell with the calibrated reference volume, and the pressure drops to a system equilibrium P_3 :

$$P_3(V - V_s) + P_3V_R = n_2RT + n_RRT \quad (\text{Eq 5})$$

Substituting PV_R from Eq 2 for n_RRT in Eq 5 and substituting $P_2(V - V_s)$ from Eq 4 for n_2RT results in:

$$P_3(V - V_s) + P_3V_R = P_2(V - V_s) + PV_R \quad (\text{Eq 6})$$

Simplifying:

$$(P_3 - P_2)(V - V_s) = (P - P_3)V_R \quad (\text{Eq 7})$$

$$V - V_s = \frac{(P - P_3)V_R}{(P_3 - P_2)} \quad (\text{Eq 8})$$

$$V_s = V + V_R/[1 - (P_2 - P)/(P_3 - P)] \quad (\text{Eq 9})$$

Because P is "zeroed" at ambient before pressurizing, the working equation becomes:

$$V_s = V + V_R/[1 - (P_2/P_3)] \quad (\text{Eq 10})$$

Over the last few years, the gas pycnometer has been further improved by using a more accurate pressure transducer, a better temperature control of the entire system, and by an automation (computerization) of the actual analysis process. Modern pycnometers can now reach an accuracy of 0.01%.

Surface Area, Density, and Porosity of Powders

Mercury Porosimetry

H. Giesche, School of Ceramic Engineering and Sciences, Alfred University

Many commercially important processes involve the transport of fluids through porous media and the displacement of one fluid, already in the media, by another. The role played by pore structure is of fundamental importance in understanding of these processes. The quality of powder compacts is also affected by the void size distribution between the constituent particles. For these reasons, mercury porosimetry has long been used as an experimental technique for the characterization of pore and void structure.

Gas and mercury porosimetry are complementary techniques with the latter covering a much wider size range from 0.3 mm to 3.5 nm (Fig. 10). Mercury porosimetry consists of the gradual intrusion of mercury into an evacuated porous medium at increasingly higher pressures followed by extrusion as the pressure is lowered. The simplest pore model is based on parallel circular capillaries that empty completely as the pressure is reduced to zero. This model fails to take into account the real nature of more porous media, which consist of a network of interconnecting noncircular pores. The network effects lead to hysteresis and mercury retention during the extrusion cycle.

Fig. 10 Pore radii ranges covered by gas and mercury porosimetry

Surface Area, Density, and Porosity of Powders

General Description

Relationship between Pore Radii and Intrusion Pressure. Mercury porosimetry is based on the capillary rise phenomenon whereby an excess pressure is required to cause a nonwetting liquid to enter a narrow capillary. The pressure difference across the interface is given by the equation of Young (Ref 31) and Laplace (Ref 32), and its sign is such that the pressure is less in the liquid than in the gas (or vacuum) phase if the contact angle θ is greater than 90° or more if θ is less than 90° . If the capillary is circular in cross section, and not too large in radius, the meniscus will be approximately hemispherical. The curvature of the meniscus can be related to the radius of the capillary, and the Young-Laplace equation reduces to the Washburn equation (Ref 33):

$$\Delta P = \gamma_{lv} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) = \frac{2\gamma_{lv}}{r_p} \cos \theta \quad (\text{Eq 11})$$

This is the Young-Laplace and Washburn equation where γ_{lv} is the surface tension of the liquid (e.g., for mercury, 0.485 N/m), r_1 and r_2 are mutually perpendicular radii of a surface segment. The angle θ is the angle of contact between the liquid and the capillary walls and is always measured within the liquid (Fig. 11). r_p is the capillary radius.

Fig. 11 Contact angle (θ) of a liquid in a capillary

Equipment Fundamentals. The sample is placed into the penetrometer assembly; it is then evacuated to a set vacuum level for a specific time, before the sample cell is filled with mercury. Air is admitted to the low-pressure chamber, and the increasing pressure forces the mercury to penetrate the largest pores of the sample. The amount or volume of mercury penetrating into the sample is recorded at each pressure (or pore size) point; the first reading usually is taken at a pressure of 0.5 psi (0.003 MPa), although readings at a pressure of 0.1 psi (0.7×10^{-4} MPa) are possible. The pressure is then increased to 1 atm, or in some instruments the pressure is actually increased to a slight overpressure (up to 50 psi in some cases). After the low-pressure run is finished, the penetrometer is then inserted into a high-pressure port and surrounded with a special grade of high-pressure oil; it is special with respect to the dielectric constant and viscosity of the oil under high-pressure conditions. The pressure is increased up to a final pressure of 60 ksi (400 MPa). Commercial instruments work either in an incremental or continuous mode. In the former, the pressure is increased in steps and the system allowed to stabilize at each pressure point before the next step. In the continuous mode, the pressure is increased continuously at a predetermined rate. Schematics of low-pressure and high-pressure systems are shown in Fig. 12 and 13, respectively (Ref 34).

Surface Area, Density, and Porosity of Powders

Measurement Techniques

Measuring Displacement Volumes (Pore Volume). Mercury volume displacements may be measured by direct visual observation of the mercury level in a glass penetrometer stem (Fig. 14) with graduated markings (Ref 35). However, most (if not all) instruments on the market will measure this volume automatically by one of the following techniques:

- *Precision capacitive bridges*: measure changes in the capacitance between the column of mercury in a dilatometer stem and a coaxial sheet surrounding the column
- *Mechanical transducer*: indicate the change in height of the mercury column by moving a contact wire and measuring the displacement of the mercury interface in the stem
- *Submerged wires*: measure changes in resistivity corresponding to the change in length of the mercury column

From a practical point of view, the sample mass (pore volume) and the stem volume of the penetrometer should be adjusted to use the instrument to its highest resolution. In general, larger samples are preferred because they provide a better representation of the overall sample.

Fig. 14 Quantachrome filling mechanism and low-pressure porosimetry system. Source: Ref 35

Pressure. The corresponding pressure at which mercury is filling the pore system is usually measured with electronic pressure transducer or with Heise-Bourdon manometer, used in older manual setups. A series of those pressure transducers ensures that accurate data are determined over the entire range from 0.1 psi (0.7×10^{-4} MPa) to 60 psi (0.4 MPa).

Looking at the Washburn equation (Eq 11) makes it obvious that two additional parameters play a critical role in the calculation of pore size from the applied pressure: contact angle, θ , and the surface tension, γ_{Hg} .

Contact Angle Determination. Various techniques are available to determine the contact angle:

- A drop of mercury can be placed on the flat surface of the sample, and the resulting contact angle is visually observed. Problems related to "micro" and "macro" contact angles have been reported (Fig. 15) (Ref 36). Brashforth and Adams (Ref 37) published tables that allow calculation of the contact angle as well as the surface tension of liquids from the shape of a drop of mercury on the substrate surface (Fig.

16). A simplified formula can be used when the maximum height of the drop is reached (Ref 35, 37, 38):

$$\cos \theta = 1 - \frac{\rho g h_{\max}^2}{2 \gamma_{lg}}$$

- with g , the acceleration of gravity, and ρ , the density of the liquid.
- A powder compact can be pressed in such a way that a well-defined hole is created in a disk. Mercury is now placed on top of this disk, and the contact angle can be calculated from the necessary pressure to force the mercury through this cylindrical pore.
- The Willhelmy plate method (Fig. 17) can be used to determine the contact angle (Ref 39). Figures 17 and 18 illustrate the critical observation of an advancing and receding mercury interface. Surface roughness (Fig. 18) or the change in surface composition during the contact with mercury can explain the presence of this difference. (Note: there is no thermodynamic reason or explanation for any contact angle hysteresis.) No surface roughness effects are assumed below pore sizes of about 100 nm. This effect also emphasizes the importance of clean samples and clean mercury.

The contact angle between mercury and the sample being tested is frequently assumed to be 130 or 140°. This assumption is probably the largest source of error. Contact angles of different materials may differ significantly, as shown in Table 2 (Ref 40).

Table 2 Contact angle between mercury and select P/M materials

Powder	Angle, degrees
Aluminum	140
Copper	116
Glass	153
Iron	115
Zinc	133
Tungsten carbide	121
Tungsten	135

Source: Ref 40

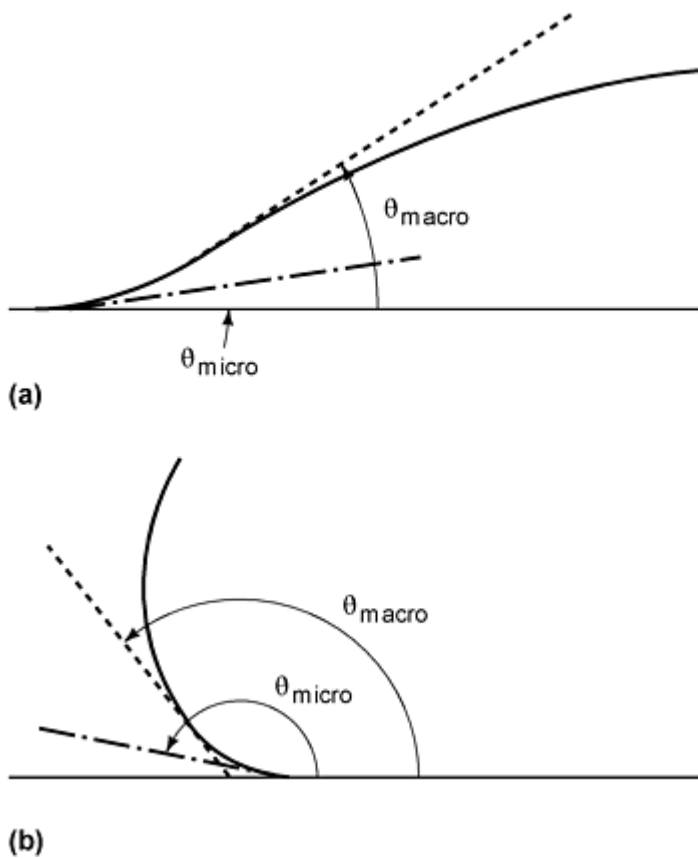

Fig. 15 Differences between microscopic and macroscopic measurement of the contact angle (θ) under conditions of (a) wetting and (b) nonwetting

Fig. 16 Change of mercury-drop shape with size

Fig. 17 Wilhelmy plate method showing the effect of contact angle hysteresis for emersion and immersion. Adapted from Ref 39

Fig. 18 Effect of surface roughness on contact angles

The Washburn equation is directly proportional to the cosine of the contact angle; the respective pore size errors for iron ($\theta = 115^\circ$) and glass ($\theta = 153^\circ$), using the values from Table 2 versus a constant value of 130° for θ , would be:

$$52\% = \frac{\cos 130 - \cos 115}{\cos 153} 100$$

or

$$28\% = \frac{\cos 153 - \cos 130}{\cos 153} 100$$

However, published contact angles differ widely between different research groups, even when presumably the same material was studied.

Some materials might react with mercury, for example, zinc, silver, or lead samples. This severely changes the nonwetting behavior of mercury with that sample and may even lead to a contact angle of $<90^\circ$. In those cases a protective film of stearic acid can be applied to the sample/pore surface and thus prevent the reaction. Though, for several reactive metals, such as copper, their natural oxide layer on the surface is a sufficient protection (Ref 41).

Surface Tension of Mercury. Values for the surface tension of mercury can vary with atmosphere, temperature, and purity of the mercury used. The purity of mercury has a significant effect on surface tension. Reported values vary by up to 0.1 N/m (100 dynes/cm). Mercury is unusually prone to contamination, and this probably accounts for the lack of reproducibility to be found in the values of surface tension in earlier publications. Later work, however, showed very consistent results (Table 3) (Ref 6). The effect of temperature is minimal, because the temperature coefficient of the surface tension of mercury is only 2.1×10^{-4} N/m \cdot $^\circ\text{C}$. Another error is caused by neglecting the change of surface tension for very small radii of surface curvature. The following correction has been suggested by Kloubek (Ref 42):

$$\gamma_{\text{corr}} = \gamma - 2.66 \times 10^{-4} \text{ m} \cdot \Delta P$$

For $\Delta P = 200$ MPa, the correction term gives an error of 12% [$\gamma_{\text{corr}} = (0.485 - 0.053)$ N/m].

Table 3 Surface tension of mercury in vacuum

Compressibility of Mercury. Due to the slight compressibility of mercury, the measured pore volume of a porous material appears larger than its actual volume. Using a well-balanced combination of the compressibility of the glass sample cell, the mercury and the changes of dielectric properties especially of the high-pressure fluid minimizes this blank effect. In general, the larger the sample and pore volume of the sample in comparison to the amount of mercury in the penetrometer, the smaller the errors due to compressibility. Moreover a blank run correction can be used to correct for compressibility effects. However, the total effect is a combination of all components in the system: the mercury, the high-pressure oil, the glass penetrometer, and the sample.

Surface Area, Density, and Porosity of Powders

Restrictions and Limitations (Ref 43)

Results obtainable by mercury porosimetry are limited a priori in three ways:

- The volume of pore space filled with mercury is limited by the maximum pressure. This aspect is related to the question of what is to be counted as pore space; this is not self-evident for all materials (e.g., cement stone). Mercury cannot penetrate very small pores.
- At the other end of the scale, the penetration of very large pores is limited by the height of the sample, which determines a minimum pressure. Hence, very large pores may go unnoticed. (This was observed, e.g., for porous nickel plaques.)
- The sample size is finite and usually quite small. This boundary condition determines that results are not necessarily representative of an infinite pore space, as large pore openings (at the surface) are more easily accessible in a smaller sample. Empirical support for this has been found by carrying out experiments with jacketed and unjacketed samples.

Geometrical properties of the sample can affect the reproducibility and can cause difficulty in giving an unambiguous interpretation of the result:

- In many cases, a distinction is to be made between the interparticle and intraparticle voids. In a packing of nonporous particles there is only an interparticle pore space. However, in many applications--for example, sorbents--the prime concern is in the intraparticle void space. In such cases, a judgment must be made as to which part of the measured pore volume belongs to the interparticle voids and which part belongs to the intraparticle porosity. If the sample exists as larger particles, the pore size distribution frequently shows a bimodal pore size distribution. The larger pore size fraction can then be attributed to the interparticle porosity. It may also help to use a narrow size fraction of these particles for the porosity analysis. A narrow particle size distribution causes a distinct peak in the pore size distribution at about 20 to 50% of the particle size, which can be clearly attributed to the interparticle voids.
- A special problem is caused by the roughness of the surface of the particles or lumps that are measured. Reich (Ref 44) already pointed out that characterization of samples should be based on those with the same surface roughness. He found a significant difference for pieces of brick broken in different ways. Corrections for the "part of the surface" that belongs to the particle pore space have been made, but it remains difficult to separate pores at the surface from pores in the inside if a cross-sectional area through the surface is different from a cross-sectional area through the interior of the porous medium. Sometimes these differences are very great, and the presence of a characteristic surface layer can actually be observed.
- Pretreatment of the sample may involve comminution. This may change the internal pore space in two ways. First, if closed pores are present, some of these will be broken open. Second, particles tend to break along large pores; hence the relative volume of larger pores decreases.
- Similar problems arise for nonparticulate materials such as paper. Sheetlike material should be packed in a controlled way to eliminate artificial pores between the sheets.

The points mentioned up to now are basically limitations of the technique. If they are overlooked, they can lead to errors of interpretation. The following is a list of factors that can upset the accuracy and the reliability of the results in a more direct way.

- Even if clean mercury is used at the beginning, the surface may soon be contaminated by components that were adsorbed on the surface of the sample. It is known that impurities can change the surface tension of mercury by as much as 30%.
- Before mercury enters the dilatometer, the sample should be outgassed. Evacuation of the sample can change the contact angle of the sample (compared with the contact angle on the sample in its original condition). It has been stated that strong outgassing is necessary if the smallest pores are to be measured. However, the error caused by compression of residual air seems to become significant only if the evacuation does not reach a pressure below 10 torr.
- A serious problem arises when the sample is mechanically destroyed by the applied pressure during the analysis. Fragile porous materials may be subject to a breakdown of pores during pressurization, or sol-gel materials are frequently compressed reversibly or irreversibly during the mercury porosimetry analysis at high pressure. Knowledge of the compressibility or fracture strength of the material to be analyzed is desirable to properly estimate whether mercury intrusion will occur before deformation or fracture of the porous material occurs. In other cases, a powder compact can be further compacted during the measurement; for example, a powder was compacted at a pressure of 10 MPa; however, mercury does not penetrate the pores before a pressure of 20 MPa is reached. In this case, the sample experiences a second compaction and the results are not related to a compaction pressure of 10 MPa but rather 20 MPa.
- Corrections have to be made for the compressibility of the dilatometer and the mercury, as well as compressibility effects of the sample. Due to the compression of the mercury and oil, the temperature in the dilatometer may rise considerably when a high pressure is applied. It has been estimated that the temperature rise could be as much as 15°. Although it has occasionally been mentioned that a cooling fan is used, this point seems to have gone largely unnoticed. A change in temperature then changes the volume of the mercury and the dilatometer and thus causes an artificial pore volume effect.
- The so-called kinetic hysteresis effect is related to the time that is required for the mercury to flow into pores. If a volume reading is taken before equilibrium has been reached, this will result in a shift of the

pore size distribution toward smaller values.

Moreover, the rate of advance of mercury interfaces in horizontal, cylindrical capillaries was computed and also verified experimentally. For a given sample size and pore size, the time required for equilibrium to be achieved during injection can be calculated.

For a horizontal, cylindrical capillary, mercury enters the capillary at the threshold pressure, as given by the Laplace equation, but does not continue to advance. A finite rate of advance is dependent on an excess pressure (ΔP) above the threshold pressure and the distance-to-time relationship for the advancing mercury front is given by the following equation, which can be derived from the Poiseuille equation (see Ref 39, p 286, and Ref 49):

$$t = \frac{l^2 4\eta}{\Delta P r_p^2}$$

where t is time, l is distance, η is viscosity, r is radius, and ΔP is pressure applied in excess of the injection pressure.

The distance-to-time relationship for mercury in tubes of five different sizes is shown in Fig. 19. A total applied pressure of 110% of the injection pressure--that is ΔP in the previous equation is equal to 10% of injection pressure given by the Laplace equation--was used. The graph shows that for a tube of $0.5 \mu\text{m}$ radius, the time required to travel 3 cm is in excess of 100 s.

Fig. 19 Distance-to-time ratio for mercury advancing in tubes of five different radii (r). Source: Ref 49

The measured data are not reliable if they do not refer to an equilibrium situation. In older publications, for example, kinetic hysteresis is stressed and the effect of mechanical vibrations ("tapping") is noted. In practice, those limitations only apply to very large samples or for extremely small pore sizes. An equilibration time of 1 to a maximum of 5 min should be sufficient in all samples.

In general, effects due to different intrusion rates are not very severe. However, an example where pore size as well as pore volume was greatly influenced is shown in Fig. 20. Five samples of an alumina extrudate were analyzed with different equilibration routines. One sample was scanned (equilibration by time for 0 s). Three others were analyzed at different equilibration intervals (2, 10, and 30 s), and a fourth was analyzed at an equilibration rate of 0.001 $\mu\text{L/g} \cdot \text{s}$. The data from the five experiments are summarized in Fig. 20.

Surface Area, Density, and Porosity of Powders

Surface Area Determination

Under the assumption of a specific pore geometry, one can calculate the surface area of a sample from mercury porosimetry measurements. Usually the cylinder pore model is used.

Rootare and Prenzlöw (Ref 45) derived the following equation:

$$\text{Area} = -\int_0^V \frac{P dV}{\gamma_{lv} \cos \theta}$$

This equation is equivalent to the cylinder pore model.

The later derivation does not contain an assumption about the pore geometry; it does however, assume that the movement of the mercury meniscus is reversible. For an interconnected pore system, this is not the case and the equation will always calculate higher values for the surface area. Surprisingly many publications report a relatively good correlation between surface area values derived from mercury porosimetry measurements and corresponding N₂-gas adsorption BET values (Ref 6, 45) (Table 4).

Table 4 Comparison of surface area measurements with N₂ gas adsorption and Hg porosimetry

Sample	Surface area, m ² /g	
	Hg-porosimetry	N ₂ -adsorption
Tungsten powder	0.11	0.10
Iron powder	0.20	0.30
Zinc dust	0.34	0.32
Copper powder	0.34	0.49
Silver iodide	0.48	0.53
Aluminum dust	1.35	1.14
Fluorspar	2.48	2.12
Iron oxide	14.3	13.3
Anatase	15.1	10.3
Graphitized carbon black	15.7	12.3
Boron nitride	19.6	20.0
Hydroxyapatite	55.2	55.0
Carbon black (Spheron-6)	107.8	110.0

The value of the specific surface area is often used to determine ("adjust") the contact angle of mercury on a specific material by modifying the contact angle until the surface area calculated from mercury porosimetry measurements correlates with the values determined from nitrogen adsorption data. For materials that do not indicate a severe effect of compressibility or pores smaller than about 10 nm, this method might be a valid alternative to determine the contact angle.

Hysteresis and Entrapped Mercury in the Sample. Interpretation of the extrusion data from mercury porosimetry measurements has been mostly neglected because the interpretation was very vague and questionable. Traditionally, three theories are used to explain the hysteresis between the intrusion and extrusion curve in mercury porosimetry measurements (Fig. 21) (Ref 48): contact angle hysteresis, ink-bottle theory, and connectivity model.

Fig. 21 Mercury porosimetry analysis of an ordered packed sphere structure. Source: Ref 48

Contact Angle Hysteresis. Numerous authors have reported different values for advancing and receding contact angles (Fig. 22). The problem, however, is much more complicated because thermodynamic reasoning does not support such a difference. In addition, the observed intrusion and extrusion curves do not fit as perfectly as they should according to the contact angle hysteresis model. Moreover, the model does not provide any explanation for the trapped mercury, which may remain in the sample even after complete depressurization.

Fig. 22 Hysteresis model based on differences in advancing and receding angles

The ink-bottle theory accurately describes the situation in which mercury enters and leaves pores (Fig. 23). It explains why some of the mercury remains trapped in the sample. However, it explains the principal hysteresis only in part. For most samples, the ink-bottle theory would predict a much larger amount of mercury remaining in the sample than actually observed in the measurement. The contradiction has not been resolved.

Fig. 23 The ink-bottle theory of hysteresis when mercury enters and leaves the pores

The connectivity model uses a network of pores. In order for a pore to become filled with mercury, it is essential to be larger than the corresponding pore size at the applied pressure, but it is also necessary that a continuous path of mercury leads to the pore. Large internal voids that are surrounded by smaller pores are not filled unless the pressure is sufficient to fill the smaller pores. During the extrusion process, the reverse process can occur, and certain pores or islands of pores remain filled with mercury.

The connectivity model probably best describes the real situation, but conflicting results have been reported as well. Several new approaches have been studied recently, and further details are given in the corresponding publications (Ref 46, 47, 48, 49). Analysis of the extrusion curve as well as a back-and-forward pressure scanning within the hysteresis is presently studied. This technique can provide a better understanding of the pore and network structure of the sample.

Surface Area, Density, and Porosity of Powders

Conclusions

Mercury porosimetry is a very valuable technique, especially because it covers an extremely wide pore size range (Fig. 10). It certainly has its limitations, but carefully set experimental process conditions and a sensible data analysis provide valuable information about the sample. It is recommended that standard procedures be followed, for example, ASTM

standards D 4284 (Ref 50) and C 493 (Ref 51). A good overview on mercury porosimetry with respect to different materials and other aspects of the technique is given in several articles in Ref 52.

It is recommended that close attention be paid to a correct and meaningful data presentation. The differential plot of the pore size distribution can easily lead to a misinterpretation of the results if the graph is calculated with the "wrong" axis:

- A Δ pore volume/ Δ log (pore size) should be used to represent the differential distribution equivalent to the cumulative distribution when using a logarithmic axis for pore size.
- Using Δ pore volume/ Δ pore size leads to an overestimation of small pores.
- Plotting the pore volume versus applied pressure on a linear pressure axis allows determination and recognition of compressibility effects of the sample or the mercury.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Introduction

THE P/M INDUSTRY has grown considerably in the past decade. As a result of this growth, more critical components in the automotive, aircraft, tooling, and industrial equipment industries are being considered for manufacture using this technology. This is placing increasingly stringent quality requirements on the final P/M part. Variations in part density, mechanical properties including strength, wear, and fatigue life, as well as in aesthetic appearance and dimensional accuracy are no longer tolerated. As a result, metal powder producers and P/M part manufacturers must continually improve their capabilities to ensure the delivery of a consistent, uniform product. Research has demonstrated that these part qualities are significantly affected by changes (variations) in the particle size distribution, particle shape, and consequently the uniformity of powder blends (a combination of one or more particle sizes of a single powder) and mixes (a combination of one or more types of powders) (Ref 1, 2).

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Powder Flow

This article reviews the general factors of powder flow, and the following properties are discussed, along with examples of their applications in equipment selection:

- Cohesive strength
- Frictional properties
- Bulk density
- Permeability and flow rate
- Sliding at impact points
- Segregation tendency
- Angle of repose

The flow of metal powders in bins, hoppers, feeders, chutes, and conveyors is not always reliable or uniform. This often results in the press having to operate at lower cycle times, wasted product due to composition or apparent density variations, and operational nightmares. The powder may form a stable arch or rathole; particle segregation may occur, resulting in unacceptable variations in the bulk density of the powder supplied to the feed shoe, or the powder may flood uncontrollably.

Bulk Properties. One of the main reasons that powder flow problems are so prevalent is lack of knowledge about the bulk properties of various powders. For many engineers, the name of a powder, such as atomized aluminum, is thought to connote some useful information about its handling characteristics. While this may be true in a general sense, it is not a

reliable tool. Unfortunately, major differences in flowability often occur between different grades and types of powders with the same name.

For those who go beyond the generic name of a powder, one or more of the following four attributes are often relied on in trying to predict the behavior of metal powders and other bulk solids. However, these attributes rarely provide engineers with direct assistance during the design or specification of a bin, hopper, feeder, chute, or conveyor.

Angle of Repose. Determining the angle of repose is relatively easy: simply form a pile of material and measure its slope. Knowing what to do with the data is the difficult part.

For most materials, the angle of repose varies significantly, depending on how the pile was formed. Furthermore, the mechanics of pile formation bear little resemblance to the formation of an arch or rathole in a bin or hopper, uniformity of die fill, powder homogeneity, or to the other key parameters needed when designing a material handling system. In general, the angle of repose of a material is not an accurate measure of its flowability.

Flow Rate. The Hall and Carney flowmeters (described later in this article) are widely used in the P/M industry to characterize powder flowability. However, there are two major flaws with this approach:

- If a powder will not flow through the funnel, no information on its flowability can be determined.
- Even if a powder does flow well, the value obtained (s/50 g) cannot be extrapolated to predict limiting press speed, limiting flow rate through a feed hopper, or other rate-limiting phenomena.

The attempt to combine measurements of two material flow properties (minimum orifice size and flow rate) result in a method that does not measure either one very well.

Apparent Density or Tap Density. Neither of these parameters, nor their ratio (the Hausner Ratio), is a direct indicator of powder flowability. They do not, for example, assist in sizing hopper outlets or calculating appropriate hopper angles.

Free-Flowing versus Nonfree-Flowing. Whether or not a metal powder is considered free-flowing depends to a large extent on the size and shape of the die cavity into which it is expected to flow. For example, a powder that flows through a Hall flowmeter might be considered free-flowing; however, that same powder may have difficulty completely filling a die cavity for a thin-wall part. Thus, these terms are relative and not absolute indicators of powder flowability.

Flow Pattern Considerations. There are two flow patterns that can develop in a bin: funnel flow and mass flow. Both patterns are shown in Fig. 1.

Fig. 1 Two flow patterns that can occur in a bin: funnel flow and mass flow

In funnel flow, an active flow channel forms above the outlet with nonflowing material at the periphery. As the level of material in the hopper decreases, layers of the nonflowing material may or may not slide into the flowing channel, which can result in the formation of stable ratholes. In addition, funnel flow can cause product caking, provide a first-in-last-out flow sequence, and increase the extent to which sifting segregation impacts the discharging material.

In mass flow, all of the material is in motion whenever any is withdrawn from the hopper. Material from the center as well as the periphery moves toward the outlet. Mass flow hoppers provide a first-in-first-out flow sequence, eliminate stagnant material, reduce sifting segregation, provide a steady discharge with a consistent bulk density and a flow that is uniform and well controlled. Requirements for achieving mass flow include sizing the outlet large enough to prevent arching and ensuring the hopper walls are sufficiently smooth and steep enough to promote flow at the walls.

Useful Bulk Flow Parameters. Armed with information about the bulk properties of the powder, engineers can optimize the selection of storage and handling equipment. These same properties can be used to retrofit existing processes to correct flow problems.

Discussed below are several bulk solids handling properties that are relevant to predicting flow behavior. The direct application of these parameters has been proven over the last 30 years in numerous installations handling the full spectrum of powders used in the P/M industry, including metal powders, fine chemical additives, polymers and waxes, and graphites/carbons (Ref 3, 4).

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Cohesive Strength

Many metal powders and other bulk solids, when poured from a box, flow like a liquid. Under these conditions, such a material has no cohesive strength. However, when squeezed in the palm of one's hand, the material may gain enough strength to retain its shape once the hand is opened.

A similar range of conditions occurs inside bins, hoppers, and containers. Consolidation pressures range from zero at the surface to relatively large values at increasing depth within the container. If a powder gains cohesive strength because of the pressures applied to it, an arch or rathole can form (Fig. 2).

Fig. 2 Examples of no-flow situations where the darkened areas represent material within the bin. (a) Cohesive arch at the outlet of a bin. (b) Stable rathole formed within bin

An arch (also called a bridge or dome) is a stable obstruction that forms over the point of narrowest cross section of the storage vessel (usually the discharge outlet). The arch supports the rest of the bin contents, preventing discharge.

A rathole is a stable pipe or vertical cavity that empties out over the outlet. Material is left stranded in stagnant zones that usually remain in place until an external force is applied to dislodge them.

Cohesive strength can be measured as a function of the applied consolidation pressure. This relation, which is of primary importance in the analysis of flow, can be described as follows: suppose that a quantity of a metal powder has been placed in a cylindrical mold of cross-sectional area A , with frictionless walls (Fig. 3), and consolidated under a force $(p \times A)$ applied to the piston. Now suppose that, without disturbing it, the consolidated cylinder of powder is removed from the mold and placed on a table, and a compressive force is applied to it (Fig. 3). The force is increased from zero until the cylinder collapses at some value of the force $(f \times A)$. The experiment is repeated for several values of p . For each value of

p , a corresponding value of f is obtained. Points (p, f) are plotted in Fig. 4, and a smooth line is drawn through them. This relation is called the flow-function (FF) of the solid.

Fig. 3 An idealized flow function test. (a) Consolidation. (b) Failure

Fig. 4 Solids flow function (FF) and hopper flow factor (ff). See text for details.

This compression test serves well as an illustration of the concept, but is not practical for a number of reasons; for instance, a mold cannot be made frictionless, and it is difficult to obtain uniform consolidation of a powder in a relatively tall cylinder. In addition, most metal powders have such low cohesive strength that the compacted cylinder of powder would fall apart when it was removed from the cylindrical mold.

A more accurate and controlled procedure is described in ASTM D 6128 (Ref 5). In a laboratory, a sample of the powder is placed in a Jenike shear cell (Fig. 5), and both compressive and shear loads are applied to simulate flow conditions in a container.

Fig. 5 Jenike shear cell in initial offset shearing position

The shear cell, Fig. 5, is composed of a base located on the frame of the machine, a ring resting on top of the base, and a cover. The bottom of the cover and the inside of the base are roughened to increase friction with the tested powder. The base and the ring are filled with the powder to be tested, and a vertical load is applied to the cover. A horizontal shearing force is applied by means of a stem, which acts on a bracket attached to the cover. This shearing force, which acts in the plane of contact between the ring and the base, is partly transferred from the bracket to the ring through a loading pin. This ensures a sufficiently uniform distribution of the shearing force across the cell. The standard shear cell is 95 mm (3.75 in.) inside diameter, but a 65 mm (2.5 in.) diameter is also often used.

A shear tester is equipped with a shear cell, a gravity vertical loading system, and an electronic shearing force applicator. The applicator in the Jenike shear tester has a shearing rate of 2.54 mm/min (0.10 in./min). The shearing force necessary to maintain the strain rate is continuously recorded on a strip-chart recorder. This arrangement produces a permanent record of the stress-strain relations for each test.

Following the simplified example (described above) of testing using a cylindrical mold, shear testing is a two-step process involving consolidation (also called preshear) and shear.

Consolidation is carried out in two stages. The purpose of the first stage, called preconsolidation, is to prepare a uniform specimen. With the cover off the test cell, a packing mold is placed on top of the ring, and both the mold and the ring are placed in an offset position on the base, as shown in Fig. 6. A sample of the tested powder is then placed in the cell. One layer after another is slightly packed with the fingers, up to the top of the mold. The excess material is scraped off level with the top of the mold, and a twisting top is placed over the powder. A vertical force is applied to the top by means of a weight hanger. This force causes a vertical pressure σ_t in the material. By means of a special wrench, a number of oscillating twists is applied to the cover. This preconsolidates the powder and ensures a uniform specimen.

Fig. 6 Jenike shear cell with mold ring and consolidation lid set up for pre-consolidation

Consolidation is completed in the second stage by causing the specimen to flow under given stresses until a steady state is reached, or closely approached. This is attained in the following way: The twisting load is taken off, the twisting top and the mold are removed, the excess material is scraped off level with the top of the ring, and the test cover is placed on the material. A smaller load is now placed on the cover, and the stem of the shearing device is advanced against the bracket (Fig. 5). This smaller load compacts the sample to a preshear normal stress of σ_p .

As shearing proceeds, a condition is reached when a layer of the powder across the whole specimen is caused to flow plastically: the recorded shearing stress reaches a steady value τ_p . Consolidation determines point (σ_p, τ_p) , (Fig. 7).

Fig. 7 Yield locus (YL) showing valid shear testing points

Shear. When consolidation is completed, the stem of the shearing force device is retracted. The preshear normal stress σ_p is replaced by a smaller normal stress σ_s to locate a useful point (σ_s, τ_s) of the yield locus (Fig. 7). The sample is now sheared until a failure plane has developed. This fact is indicated on the recorder by the stress τ_s passing a maximum value. After shearing, the plane of failure of the specimen is checked. It should roughly coincide with the plane of shear of the cell. If the planes deviate, it means that the measured point (σ_s, τ_s) does not lie on the yield locus, and the test is repeated.

The determination of one yield locus requires the measurement of three to five points of the locus $(\sigma_s, \tau_s)_1, (\sigma_s, \tau_s)_2, (\sigma_s, \tau_s)_3$ and so forth (Fig. 7). For each point, the specimen is first consolidated and then sheared. The value of shear normal stress σ_s typically ranges between 25 and 80% of the preshear normal stress σ_p . It is necessary to obtain the values of these points for the same steady consolidating shear each time. This is accomplished by running a sufficient number of tests to permit interpolation to a suitably selected value of τ_p .

The yield locus is now drawn and extrapolated toward the higher value of σ_p , and a Mohr semicircle is drawn through point (σ_p, τ_p) tangentially to the yield locus. The point of tangency (E) locates the terminus of the yield locus. The point of intersection of the semicircle with the σ -axis determines the value of the major consolidation stress, σ_1 . The Mohr semicircle for the unconfined yield strength f_c is now drawn. The value of f_c is determined by the point of intersection of the circle with the σ axis, as shown in the Fig. 7.

A plot of f_c versus σ_1 is the flow function of the powder under the conditions of particle size, moisture, and temperature tested.

To simulate time of storage at rest, the shear tester is used in conjunction with a six-cell consolidating bench (Fig. 8). The tester shown in Fig. 9 is used for temperature sensitive solids. Here, the consolidating bench is enclosed in a heated chamber that permits the control and recording of the temperature of the tested powder.

Fig. 8 Consolidation bench

Fig. 9 Consolidation bench in heated chamber

The flow function of a powder is used for a variety of engineering analyses, for example, to calculate minimum outlet dimensions required to prevent cohesive arches and ratholes from forming. Details can be found in Ref 3.

The cohesiveness of a bulk solid is a function of the following parameters:

- *Moisture*: Typically, cohesiveness rises as moisture content increases, although not in direct proportion. Hygroscopic materials can experience significant increases in moisture when exposed to humid air.
- *Particle size and shape*: There is no direct correlation between particle size, shape, and cohesiveness. Even so, in most cases, as a powder becomes finer, it also becomes more cohesive and difficult to handle. Angular or fibrous particles are often more cohesive than those that are rounded.
- *Temperature*: The temperature of a powder can affect its cohesiveness. For example, many thermoplastic blends (such as for PIM) become more difficult to handle as their temperatures rise. Some materials have more strength at constant temperatures, while others gain cohesive strength as their temperature changes during heating or cooling.
- *Time of storage at rest*: When a material resides in a bin or hopper for a period without moving, it can become more cohesive and difficult to handle. Such cohesion may be caused by settling and compaction, crystallization, chemical reactions, and adhesive bonding.
- *Chemical additives*: In some cases, adding a small amount of a chemical additive such as calcium, lithium, or zinc stearates can cause a cohesive powder to flow more easily.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Frictional Properties

Both internal and external friction values are important when characterizing the flow properties of a metal powder. Internal friction is caused by solid particles flowing against each other and is expressed by the angle of internal friction and the effective angle of internal friction. Both can be determined during the course of measuring cohesive strength with a Jenike shear cell (Fig. 5), as described in Ref 5.

External friction is expressed as the wall friction angle or coefficient of sliding friction. The lower the coefficient of sliding friction, the less steep the hopper walls need to be for powder to flow along them (mass flow). Also, the easier a feed shoe indexes to and from a die, the more uniform the flow of powder into the die cavity.

The coefficient of sliding friction can be measured by sliding a sample of powder across a stationary wall surface using a shear tester. The arrangement of the cell is shown in Fig. 10. In this case, a coupon of the wall material is placed on a filler so that the top surface of the coupon is the horizontal plane of the force measuring stem. The ring and packing mold are placed over the wall material coupon and filled with the powder.

Fig. 10 Shear cell used in measuring wall friction properties. Test setup design allows shear stress (see horizontal arrow) to be measured as a result of applied weights (see vertical downward arrow).

After scraping off the excess material level with the top of the mold, a twisting top is placed over the powder. A vertical force is applied to the top by means of a weight hanger. This force causes a vertical pressure σ_v in the material. By means of a special wrench, a number of oscillating twists is now applied to the cover. This preconsolidates the powder and ensures a uniform specimen.

The twisting load is taken off, the twisting top and the mold are removed, the excess material is scraped off level with the top of the ring, and the test cover is placed on the material. A smaller load is now placed on the cover, and the stem of the shearing device is advanced against the bracket (Fig. 10). All the tests necessary to determine the coefficient of sliding friction are now run without replacing the powder.

Before the start of a test, the ring is twisted and manually lifted slightly off the wall material coupon to prevent it from dragging on the wall coupon. Several (say, six) one or two pound weights are placed directly on top of the cover of the shear cell to give the largest required normal stress σ_w . The stem is advanced. When the shear stress τ_w has leveled off, one weight is removed, after a while τ_w again levels off, another weight is removed and so on, until all the weights have been removed. The cover, ring, and the enclosed powder are then weighed. Their weight plus the superimposed weights determine the normal stresses σ_w .

A typical recorder chart is shown in Fig. 11. The points (σ_w, τ_w) are plotted in Fig. 12. A smooth line drawn through these points is the wall yield locus, WYL. Typically, the WYL is convex upward.

Fig. 11 Typical recorder chart in measurement of ϕ' (wall friction angle)

Fig. 12 Typical results of the test setup shown in Fig. 10 to help engineers determine wall friction angle (ϕ')

The coefficient of sliding friction is the ratio of the shear force required to cause sliding to the load applied perpendicular to the wall material coupon. The arc tangent of this value is the wall friction angle (Ref 3, 4).

The following variables can affect the internal and external friction values of a metal powder and are similar to those affecting cohesiveness:

- *Pressure:* Typically, as consolidating pressure increases, the effective angle of internal friction decreases. Similarly, the coefficient of sliding friction often decreases as pressure acting normal to the plate increases. However, the internal angle of friction is an intrinsic characteristic of the material that may increase, decrease, or remain the same as pressure acting on the material increases.
- *Moisture content:* As moisture increases, many bulk solids become more frictional.
- *Particle size and shape:* Typically, fine materials and those with a wide range of particle sizes are somewhat more frictional than coarse materials or those with a narrow particle size distribution; so the flow of the former is often more troublesome. Shape plays a role in that angular particles tend to interlock and also dig into a wall surface, thereby creating more friction.
- *Temperature:* For many materials, higher temperatures can cause particles to become more frictional.
- *Time of storage at rest:* If allowed to adhere to a wall surface, many powders experience an increase in friction between the particles and the wall surface. Such situations require steeper bin walls for unaided flow.
- *Wall surface:* The initial condition of a surface can play a major role in how materials slide along it. Smoother surfaces are typically less frictional, although this is not always true. Also, as a carbon steel container ages, corrosion can roughen the walls, making sliding more difficult.

Friction data are used to:

- *Design a mass flow hopper:* Values of both wall friction angle and effective angle of internal friction are required to design a mass flow hopper. Using these angles along with design charts given by Jenike (Ref 3), one can determine allowable hopper angles required to promote mass flow.
- *Anticipate sliding on chutes:* A chute is used to transfer material from one point to another in a bulk handling system. By definition, the cross section of a chute is only partially full at any given time, and the discharge rate of a powder is equal to the chute filling rate.

Beyond the impact point, the acceleration of a particle on a chute is directly related to the difference between the wall friction angle of the material and the chute angle. As long as the chute is steeper than the wall friction angle, particles will continue to accelerate. Otherwise they will slow down and may eventually block the chute.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Bulk Density

Bulk density measurements of powders include apparent density and tap density measurements as described below. A key factor is compressibility.

Apparent Density

Apparent density of a metal powder, or the weight of a unit volume of loose powder expressed in grams per cubic centimeter, is one of the fundamental properties of a powder. This characteristic defines the actual volume occupied by a mass of loose powder, which directly affects processing parameters such as the design of compaction tooling and the magnitude of the press motions required to compact and densify loose powder.

In most compacting operations, dies are filled by volume measure, and presses operate either to a fixed position or a fixed pressure. If the press operates to a fixed position, pressure can be maintained at a constant level only if the apparent density of the powder does not change. If, however, the press operates to a fixed pressure, consistency in apparent density is necessary to ensure compacts of equal height. Small fluctuations in apparent density can be compensated for by adjustments of pressure or stroke of the presses, but large-scale compacting requires that the apparent density of the powder be controlled within close limits.

Factors Affecting Apparent Density. Apparent density of a metal powder depends on the density of the solid material, particle size, particle size distribution, particle shape, surface area and roughness of individual particles, and particle arrangement. Apparent density is strongly affected by particle size. It generally (1) decreases with decreasing particle size, (2) decreases as the particle shape becomes less spherical and more irregular, (3) decreases with increasing surface roughness, and (4) is frequently controlled by mixing various sizes of particles.

Particle Size. Decreasing particle size generally decreases apparent density. The smaller the particles, the greater the specific surface of the powder. This phenomenon increases the friction between particles and subsequently decreases the apparent density. Powder particles that exhibit very low friction because of their rounded shape, such as gas-atomized (spherical) stainless steel powder, do not demonstrate this characteristic. The effect of decreased particle size on density is particularly significant for particle sizes of less than 20 μm . Table 1 shows the effect of particle size on apparent density for several metal powders.

Table 1 Effect of particle size on apparent density for several metal powders

Material	Average particle diameter ^(a) , μm	Apparent density, g/cm^3
Aluminum		
Atomized	5.8	0.62
	6.8	0.75
	15.5	0.98
	17.0	1.04

(a) From Fisher subsieve sizer for single values and screens for size fractions

Particle Shape. As particle shape becomes less spherical, apparent density decreases, due to both the increase in frictional surface area and less uniformity of powder particles during packing. Spherical powders, which are normally produced by atomizing, frequently have high apparent densities, about 50% of the density of the wrought metal. Spheres are most likely to pack without bridging or arching to create empty spaces; they tend to move easily past each other because of their smooth surfaces. At the other extreme in particle shape are flake powders, which often have apparent densities less than 10% of the wrought density. These powders are useful primarily as pigments, because their low apparent density aids in obtaining mixtures in paint.

Most powders used for compacting have irregular, somewhat equiaxed particle shapes with apparent densities that fall in the range between those of spherical and flake powders. Apparent densities of these particles range from 25 to 35% of the wrought density of the metal. Figure 13 illustrates the effect of particle shape on apparent density.

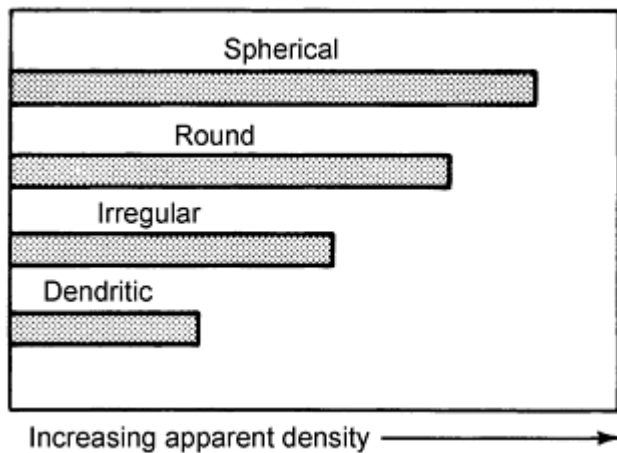

Fig. 13 Effect of particle shape on apparent density of a metal powder

Surface Roughness. Decreasing surface area-to-volume ratios and decreasing surface roughness tends to reduce frictional forces between settling particles. This tendency thus increases apparent density by allowing the particles to move more effectively to fill the free spaces between previously settled particles.

Particle Size Distribution. An effective way to increase the apparent density of a powder is to fill the spaces between particles with smaller particles. Figure 14 shows the effects of adding differently shaped -325 mesh powder to a standard +325 mesh blend of stainless steel powder. Table 2 shows this effect for mixtures of fine and coarse spherically shaped stainless steel powders, where a mixture of about 60% coarse and 40% fine particles is optimal.

Table 2 Effect of mixture of spherical coarse and fine stainless steel particles on apparent density

Particle size (mesh)	Particles, %					
	100	80	60	40	20	...
-100+150	100	80	60	40	20	...
-325	...	20	40	60	80	100
Apparent density, g/cm ³	4.5	4.9	5.2	4.8	4.6	4.3

Fig. 14 Effect of three different shapes of -325 mesh powder addition to a +325 mesh distribution on apparent density of 316 stainless powder

The addition of fine spherical powder effectively increases apparent density, while the opposite is true of flake powders. Distribution of a variety of particle sizes greatly affects apparent density. The relative amount of coarsest and finest particles and the percentage of particles between the two extremes determine apparent density. An example of this is shown in Table 3 for three particle size distributions.

Table 3 Apparent densities and flow rates of electrolytic iron powders of three particle size distributions

Particle size (mesh)	Particles, %		
	Powder A	Powder B	Powder C
+100	4	3	15
-100+150	11	26	10
-150+200	18	18	30
-200+250	16	6	25
-250+325	18	16	5
-325	33	31	15
Apparent density, g/cm ³	2.6-2.8	3.2-3.4	3.8-3.9
Flow rate, s/50 g	29	24	20

Hall Flowmeter and Carney Funnel. The most common method for determining apparent density of metal powders uses the Hall flowmeter. Both ASTM B 212 and Metal Powder Industries Federation (MPIF) standard 04 describe this method.

Critical equipment dimensions are illustrated in Fig. 15(a), 15(c), and 15(d). Apparent density determinations are made by pouring powder into the funnel and allowing it to flow into the 25 cm³ (1.5 in.³) density cup. After the cup is fitted, the funnel is moved away and the excess powder is carefully leveled off using a spatula or straight edge. Care must be exercised to prevent physical densification of the powder in the cup when leveling. The apparent density in grams per cubic centimeter is then determined by weighing the powder in the cup in grams and dividing by 25 cm³ (1.5 in.³) (cup volume).

Fig. 15 Dimensions for apparent density equipment

For powders that do not flow freely, a second method, described in ASTM B 417 and MPIF 28, has been devised. This is similar to the Hall flowmeter procedure, except that a different funnel, the Carney funnel, which has an orifice diameter twice that of the Hall funnel, is used (see Fig. 15a and b). This larger opening permits a greater variety of powders to flow. Powders that do not flow readily can be freed by poking a wire up and down in the hole. The wire must not enter the density cup at any time. This second method is fast and correlates well with the Hall flowmeter evaluation of free-flowing metal powders.

A wire is not used with the Hall flow-meter funnel because it may scratch the orifice and ruin the calibration of the funnel for flow tests. The Carney funnel is often used when measuring apparent density of lubricated powders because lubricant adhering to the smaller orifice of the Hall funnel temporarily affects the calibration of the Hall flowmeter.

Scott Volumeter. Another instrument frequently used for determining apparent density is the Scott volumeter, described in ASTM B 329, which was originally developed by Scott, Schaeffer, and White for the determination of the density of dry pigment for paint. As shown in Fig. 16, the device consists of:

- A large brass funnel with a metal screen and a smaller funnel with a straight stem for directing the powder into the baffle box
- A baffle box with glass sides and two wooden sides containing a series of glass baffle plates and a funnel

at the bottom to collect the powder and direct it into the density cup

- A *square density cup* with a capacity of $16.4 \pm 0.032 \text{ cm}^3$ ($1 \pm 0.002 \text{ in.}^3$) or a cylindrical cup with a capacity of $25.00 \pm 0.05 \text{ cm}^3$ ($1.5 \pm 0.003 \text{ in.}^3$) with an inside diameter of $30.00 \pm 2.00 \text{ mm}$ ($1.2 \pm 0.08 \text{ in.}$)
- A *stand* to support the funnels and baffle box concentric with the density cup, so that the bottom of the baffle box funnel is 19 mm (0.75 in.) above the top of the density cup when the apparatus is assembled
- A *level, vibration free base* to support the funnels and baffle box
- An *analytical balance* having a capacity of at least 100 g (3.5 oz) and a sensitivity of 0.1 g (0.0035 oz)

Fig. 16 Scott volumeter

Operating Procedure. The test specimen is carefully poured into the funnel. Ultrafine powders may require light brushing with a nylon brush to initiate powder flow through the screen in the funnel. Powder is allowed to run into the density cup until it completely fills and overflows the periphery of the cup. The funnel and baffle box should then be rotated approximately 90° in a horizontal plane to clear the cup.

Excess material should be removed from the cup by passing a spatula blade in flat contact with the top of the cup. The spatula is moved smoothly back and forth along the top of the cup until all excess powder has been removed. When insufficient powder is left for the first reverse pass to smooth the surface completely, powder on the spatula should be gently replaced on top of the cup. The spatula must be kept level at all times to prevent packing or pulling out of the powder.

After the leveling operation, the side of the density cup should be tapped lightly to settle the powder to avoid spilling. The powder is transferred to a balance and weighed to the nearest 0.1 g (0.0035 oz). The density of the powder in the density cup is given in grams per cubic centimeter if a metric cup is used, or grams per cubic inch if a nonmetric cup is used.

Arnold Meter. Another device developed to determine the apparent density of metal powders is the Arnold meter, described in ASTM B 703 and MPIF 48, which is designed to duplicate the action of a feed shoe filling a die cavity on a P/M press. A hardened, fully demagnetized steel block with a round hole having a volume of 20 cm^3 (1.2 in.^3) is placed on a sheet of glazed paper. A bronze bushing filled with powder is slid across the hole. The powder collected in the hole is then removed and weighed. Apparent density is calculated by dividing the weight by the volume of the hole.

Apparent densities obtained with this procedure, which takes less than 5 min to perform, are quite close to those values measured on powder that has filled a die cavity from a filling shoe in an automatic compacting press.

Tap Density

Tap density is defined as the density of a powder when the volume receptacle is tapped or vibrated under specified conditions. Tapping or vibrating a loose powder induces movement and separation and lowers the friction between the powder particles. This short-term lowering in friction results in powder packing and in a higher calculated density of the powder mass. Tap density is always higher than the free-flow apparent density.

Tap density is a function of particle shape, particle porosity, and particle size distribution. It is commonly included as a control specification for metal powder, but is used in other industrial applications as a practical measure of the degree of powder packing that occurs in containers.

The amount of increase from apparent to tap density depends to a great extent on particle shape. Table 4 compares the density increases for three types of copper powders. Usually, the lower the apparent density, the higher the percentage increase in density on tapping.

Table 4 Effect of particle shape of copper powders

Particle size distribution is the same for apparent and tap density values

Particle shape	Apparent density, g/cm^3	Tap density, g/cm^3	Increase, %
Spherical	4.5	5.3	18
Irregular	2.3	3.14	35
Flake	0.4	0.7	75

Source: Ref 6

Equipment and Test Procedures. Three pieces of equipment are needed to determine tap density:

- A balance with the capacity of weighing up to 100 g with an accuracy of 0.1 g
- A graduated glass cylinder with a capacity of 100 mL and an accuracy of 0.2 mL (or a smaller graduated cylinder may be used for high-density powders)
- A mechanical apparatus, such as the Tap-Pak volumeter, capable of tapping the graduated cylinder at a rate of 100 to 250 impacts per minute or, alternatively, a hard rubber slab approximately $100 \times 100 \times 5 \text{ mm}$ ($4 \times 4 \times \frac{1}{4} \text{ in.}$)

To determine tap density, a standard weight (usually 50 g) of powder is weighed to $\pm 0.01 \text{ g}$. The powder is poured into a clean, dry graduated cylinder, taking care that a level surface of powder is obtained. For refractory metal powders that have high apparent densities (above 4 g/cm^3), it is preferable to use a reduced-volume graduated cylinder (25 mL) to improve the accuracy of the results.

The powder is settled in the cylinder by mechanical or hand tapping. If mechanical tapping (Fig. 17) is used, the filled cylinder is placed in the mechanical apparatus, which is operated until no further decrease in the volume of the powder is observed. If hand tapping is used, the base of the filled cylinder is tapped squarely on a hard rubber slab until no further decrease in volume is observed. Care must be exercised to avoid loosening the surface layers of the sample during this procedure.

Fig. 17 Diagram of tapping apparatus

The volume of the fully densified powder sample in the graduated cylinder is read and used in the following calculation of tap density:

$$\text{Tap density } \rho_t = \frac{m}{v}$$

where m is the mass of powder in grams and v is the volume of tapped powder in cubic centimeters. Results should be reported to the nearest 0.1 g/cm³.

Representative tap densities of several metal powders and compounds are listed in Table 5, with their respective Fisher subsieve sizes. Mechanical tapping is performed in accordance with ASTM B 527, MPIF 46, or International Standards Organization (ISO) standard 3953. Manual tapping is performed in accordance with either the MPIF or ISO standard. Interlaboratory reproducibility of tap density values can be expected to fall within a standard deviation of about 3.5%.

Table 5 Typical tap densities of metal and metal carbide powders

Powder	Fisher subsieve size, μm	Tap density, g/cm^3
Aluminum	5.05	1.30
Chromium	3.20	3.10
Chromium carbide (Cr_3C_2)	3.70	3.50
Cobalt	1.50	1.60
Hafnium carbide (HfC)	3.50	5.95
Iron	5.40	3.55
Manganese	3.40	3.05
Molybdenum	4.30	3.75
Molybdenum carbide (Mo_2C)	4.50	3.45
Nickel	3.00	1.90
Tantalum carbide (TaC)	2.65	8.00
Tin	2.45	3.15
Titanium carbide (TiC)	3.20	3.65
Tungsten		
Fine	1.15	4.45
Coarse	6.00	6.10
Tungsten carbide (WC)		
Fine	1.45	4.20
Coarse	6.50	6.50
Tungsten-titanium carbide (WC-TiC)	3.90	4.30
Vanadium carbide (VC)	4.50	2.70
Zirconium	3.70	2.50

Compressibility

In most cases, the bulk density of a material varies continuously as a function of the consolidating pressure acting on it. Therefore, it is not sufficient to describe a material simply in terms of its apparent density or tap density. Instead, this density-to-pressure relationship can be measured (Ref 7), and the results are often expressed as a straight line on a log-log plot (Fig. 18). In the bulk solids literature, this relationship is often called compressibility, although this term has another definition in the P/M industry.

Fig. 18 Bulk density as a function of consolidation pressure (metal powder). Increasing consolidation pressure increases the bulk density.

The following variables can affect the bulk density of a material:

- *Moisture*: Higher moisture content usually makes a material more compressible.
- *Particle size and shape*: Often, the finer the bulk solid, the more dense and compressible it is. The shape of the particles can affect how they fit together, as well as their tendency to shear while being compacted.
- *Temperature*: Some materials become more compressible as their temperature increases.
- *Particle elasticity*: Elastic materials tend to deform significantly when they are compressed.

Some of the uses of compressibility data are:

- *Wall friction angle*: Bulk density values at various points in a hopper are used to calculate the pressures acting perpendicular to the hopper wall. After running a wall friction test, the wall friction angle is determined for a variety of pressures and used to calculate limiting angles in a mass flow hopper.
- *Feeder design*: To calculate the loads that act on a feeder or gate, one must know the bulk density of the material at the hopper outlet. Knowing this density also helps in sizing a volumetric feeder and choosing its speed.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Permeability and Flow Rate

Sizing a hopper outlet or feed tube to achieve the required discharge rate is more difficult, but no less important, than overcoming arching, particularly for fine powders. All bulk materials have a maximum rate at which they discharge through a hopper opening of a given size (e.g., a Hall flowmeter test). For example, for free-flowing bulk materials, a good approximation of this maximum discharge rate of a coarse material (e.g., 3 mm and larger particles), from a mass flow hopper can be predicted:

$$Q = \gamma A \{Bg/[2(1+m)\tan\theta]\}^{1/2}$$

where Q is the maximum steady discharge rate, γ is the bulk density, A is the cross-sectional area of outlet, B is the outlet diameter or width, g is the acceleration due to gravity, m is 1 for circular opening and 0 for slotted opening, and θ is the flow channel angle (measured from vertical) in degrees. This equation can be modified to take particle size into account, but this modification is only important if the particle size is a significant fraction of the outlet size (Ref 8).

Obviously most metal powders cannot be considered "coarse" materials; therefore, the above equation rarely applies in P/M applications.

For fine powders, funnel-flow bins often exhibit high discharge rates, but controlling the flow rate is always a challenge because the flow channel is not likely to be stable. As a result, the actual size and shape of the stagnant region is neither well defined nor constant. The flow channel can change size radically or collapse, creating flow rates that range from no-flow conditions to complete flooding.

Fine powders are more easily handled in a mass flow bin, whose flow channel is stable and predictable. Because all of the material is constantly moving in a mass flow bin, the flow channel is set by the shape of the bin.

However, it should be remembered that the maximum flow rate of a fine powder through the outlet of a mass flow bin is low compared with that of a coarse, granular solid. For fine materials, the expansion and contraction of voids during flow can create an upward air pressure gradient at the outlet of a mass flow bin. During discharge, this upward gradient acts against gravity, reducing the discharge rate. Such gradients do not usually form with coarser particle materials. Because coarse materials are more permeable than fine ones, air is allowed to flow freely into and out of the voids as they expand and contract.

This phenomenon can be analyzed by considering how gas flows through a bed of powder when a pressure differential occurs across the bed. When the gas velocity is low, flow through the bed is laminar, and Darcy's law can be used to relate gas velocities to gas pressure gradients within or across the bed. Darcy's law can be written in the following form:

$$u = -K \left[\frac{dp/dx}{\gamma} \right]$$

where K is the permeability factor of the bulk solid, u is the superficial relative gas velocity through the bed of solids, γ is the bulk density of the solid in the bed, and dp/dx is the gas pressure gradient acting at the point in the bed of solids where the velocity is being calculated. The permeability factor, K , has units of velocity and is inversely proportional to the viscosity of the gas. A permeability test is run by passing air (or other suitable gas) through a representative column of solids. The pressure across the bed is regulated, and the rate at which the gas flows is measured.

This approach allows the permeability of the bulk solid to be determined as a function of its bulk density. Figure 19 shows the test results for a sample of metal powder.

Fig. 19 Permeability as a function of bulk density (metal powder). Increases in bulk density reduce permeability of a material. Unless properly accounted for during bin selection, increased bulk density and reduced permeability can interrupt predictable flow.

Because mass flow bins have stable flow patterns that mimic the shape of the bin, permeability values can be used to calculate critical, steady-state discharge rates from mass flow hoppers. Permeability values can also be used to calculate the time required for fine powders to settle in bins and silos and to design solids processing vessels to purge, heat, dry, or condition bulk solids.

Testing of Flow Rate

Flow of metal powders is determined by standard methods developed by ASTM and MPIF. Flow rate is the time required for a powder sample of a standard weight (50 g) to flow under atmospheric conditions through a funnel into the cavity of a container or mold. A determination of the flow rate of a powder is important in high-volume manufacturing, which depends on rapid, uniform, consistent filling of the die cavity. Poor flow characteristics cause slow and nonuniform press feeding and difficulty in ensuring even fills of the die cavity.

Before a powder is used in production, its flow characteristics must be known because some compacting tools require a free-flowing powder, while others can be used with a relatively poor-flowing powder. The term free-flowing refers to those physical properties of a powder--such as composition, particle fineness, and particle shape--that permit the powder to flow readily into the die cavity.

If a compacting tool is designed to handle a free-flowing powder, the use of a poor-flowing powder will necessitate modification. Compacting press manufacturers provide modified hopper designs and feeding shoe arrangements to accommodate finer, poor-flowing powders such as tungsten, molybdenum, or lighter aluminum powders.

The flow of powder from the feeding shoe into the die cavity can be increased by tapping or by changing the design of the filling device. These factors, however, are not taken into consideration in conventional flow rate test procedures, which consist of determining the time required for a given weight or volume of powder to flow through a standardized funnel-shaped cup with a small orifice at the bottom.

The following sections briefly review flow-rate test methods and variables that affect flow rate. Additional coverage is available in Ref 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, and 21.

Hall Flowmeter. The device most commonly used for measuring flow rate is the Hall flowmeter (Fig. 15a), taken from ASTM B 213 and MPIF 3 (equivalent standards include ISO 4490, Japanese standard JIS 7-2502-1966, and German standard 82-69). The test equipment consists of a funnel with a calibrated hole 2.5 mm (0.1 in.) in diameter. The funnel, which is made of aluminum alloy 6061-T6, is supplied with a smooth finish to minimize wall friction.

With the help of a stopwatch and weighing balance, the flow rate of metal powders can be easily determined. A dry 50 g weight sample is transferred to the funnel, the orifice of which is covered with the operator's fingertip. The stopwatch is started when the fingertip is removed and is stopped when the last quantity of the powder leaves the funnel. The flow rate (s/50 g) of the sample is reported as the elapsed time in seconds for 50 g of powder to flow through the orifice. A powder that does not flow through a 2.5 mm (0.1 in.) orifice Hall funnel, with or without an external impulse, is said to be a nonfree-flowing powder (as per ASTM B 213 and MPIF 3 method).

The Hall funnel is calibrated using a standardized powder (150-mesh Turkish emery grit), a sample of which is supplied with the equipment. The desired hole size is obtained by precisely honing a drilled hole until a satisfactory flow rate of emery powder is obtained.

A change in surface finish and the radius of the orifice (at the junction of the wall), buildup of material on the sidewalls of the orifice, or enlargement of the hole size due to continuous use can alter the standardization of the funnel. Verification of the calibration should be performed periodically by using the standardized emery powder. Calibration of the Hall funnel with Ballotini solid glass spheres, having particle size ranges of 0.090 to 0.102 mm (0.0036 to 0.004 in.) and 0.065 to 0.090 mm (0.0026 to 0.0036 in.) diameters, has yielded flow rates of 35.6 and 33.4 s/50 g, respectively.

The feed of powder to the die is handled on a volume basis. Thus, differences in apparent densities of powders can lead to considerable variations in the weight of material filling a given volume. A test for volumetric flow-rate determination is under investigation by ASTM. Table 6 lists the flow rates of metal powders for both weight and volume basis. The volumetric flow-rate tests were carried out using the Hall flowmeter. The data in Table 6 indicate that the readings for volumetric flow rate lie within a narrower range, as compared to the Hall flow rate.

Table 6 Flow rate of metal powders through Hall and Carney funnels

Metal powder		Lubricant		Apparent density, g/cm ³	Flow rate of 50 g (2 oz) powder, s		Flow rate of 25 cm ³ (1.5 in. ³) powder through Half funnel, s	Weight of 25 cm ³ (1.5 in. ³) powder used in volumetric flow rate study		Calculated flow rate for 50 g (2 oz) powder based on volumetric flow rates, s

Many factors can affect the accuracy of the results obtained with the Hall flowmeter, such as the moist finger of an operator (use of gloves can eliminate this effect), vibration of the surface on which the flowmeter is placed, humidity and temperature, condition of the sample, uniformity of the powder mix, and alternate use of the device for unlubricated and lubricated powders. Residual lubricant film left by a lubricated powder on the flow-meter wall or orifice can affect the subsequent flow test results of an unlubricated powder.

Other problems associated with its use include:

- *Segregation of the mixture:* Because only a small sample (50 g) is used, slight changes in particle size distribution can result in widely varying and misleading values.
- *Limited flowability information:* If a powder is too cohesive to flow through the funnel, no information on the flowability of the powder can be determined. It has been estimated that up to 40 to 50% of all powder mixes used in the P/M industry will not flow through the Hall flowmeter.
- *Meaningless results:* Even if a powder does flow well, the value obtained (s/50 g) is not meaningful for many design problems. It cannot, for example, be extrapolated to predict limiting press speed, limiting flow rate through the feed hopper, or other rate-limiting phenomena.

The attempt to combine measurements of two material flow properties (minimum orifice size and flow rate) results in a method that does not measure either one very well (Ref 22).

Carney Funnel. Certain characteristics of some metal powders, such as particle shape and size distribution and lower specific gravity, may affect the powders to such an extent that they will not flow through the Hall funnel. In this case, the Carney funnel (Fig. 15b), which has the same dimensions as that of the Hall, except for a larger orifice diameter of 5 mm (0.2 in.), can be used to obtain a relative measure of the flowability of nonfree-flowing metal powders. The use of the Carney funnel, which is further described in ASTM B 417 and MPlF 28, is not a standardized test method in that there is no standard calibration procedure. However, it is used in industry to compare flow rates through a 5 mm (0.2 in.) orifice

for a variety of materials. Because there is no correlating factor to relate the data obtained using the Carney funnel with that of the Hall, the user must establish an empirical relationship between the two methods.

Other Testing Methods. A number of other devices or methods for measuring the flow rates of metal powders have been developed. Efforts have been made to design test methods for powders that do not flow through either the Hall or Carney funnel and to reflect the shop floor conditions of these powders.

One method currently under consideration by the International Standards Organization determines the filling characteristics of metal powder into cavities of increasing sizes. A powder-filled shoe is slid back and forth once on the surface of a 40 mm (1.6 in.) thick plate (placed on a paper) into which bores with diameters of 5, 7, 10, 15, 20, 25, and 30 mm (0.2, 0.3, 0.4, 0.6, 0.8, 1.0, and 1.2 in.) have been drilled.

The plate is then lifted, and the powder that has fallen onto the paper from each of the seven die cavities is weighed. When the mass of the powder is divided by the volume of the respective cavity, the filling density for each cavity is obtained. The test provides the critical diameter, that is, the dividing line between cavity diameters which will be filled at a constant apparent density and those through which the powder may not flow at all or which may result in incomplete cavity fill.

In 1956, a second test method for determining the flow rate of metal powders that do not flow through the Hall funnel was developed by Chrysler Corporation as an internal standard. The test equipment consists of a powder shoe of 102 cm³ (6.2 in.³) in volume and a pivoted lever attached to the shoe at one end and to a cam follower at the other. A four-lobed cam is connected to a gearbox and is driven by a motor. A circular opening of 12.7 mm (0.5 in.) diam (with a 3.0 mm (0.12 in.) wide bar at center) drilled on a 2.4 mm (0.1 in.) thick metal plate acts as a die opening.

To conduct the test, the powder-filled shoe is moved back and forth over the opening four times. This is referred to as a one-cycle operation. The quantity of powder passing through the opening is collected on a balance pan and weighed. The test equipment simulates the action of a production press, and flow is measured in terms of the quantity of powder that passes through the opening in one filling cycle of a shoe.

In one production example, the normal range for a bronze powder mix was 80 to 95 g (2.8 to 3.3 oz) per cycle, whereas the data of all the lots ranged from 30 to 125 g (1 to 4 oz) per cycle of operation. The test method was used to check the flow of a production mix under conditions comparable to those encountered in the production presses. The test indicated the flowability of a powder mix accurately.

The die-filling operation of a production press can be simulated by a third test method in which actual bearing die cavities are used. For the production of bearings with varying wall thicknesses and complicated shapes, the tool design should accommodate the variations in filling properties of the powder mixes. The following test procedure was found to be especially useful for complex powder mixes that may or may not flow through the Hall flowmeter.

The equipment consists of a powder shoe, which slides over a metal plate with a recessed cavity in which a series of cups (with or without core rods) can be fitted. The sizes of the resulting bearing-shaped cavities vary between 3.3 to 8.2 cm³ (0.2 to 0.5 in.³) in volume with wall thicknesses ranging from 1 to 3 mm (0.04 to 0.12 in.) and corresponding core rod diameters from 19 to 15 mm (0.8 to 0.6 in.) with a constant height of 45 mm (1.8 in.). A reference cavity of the same height is coreless, with a volume of 16 cm³ (1.0 in.³).

With the selected size of the bearing die in position, the powder shoe is mechanically traversed through the die (or cup) opening and back to the original position. The cup is then removed and weighed. The quantity of powder is divided by the total volume of the cup, and the fill density of the powder is calculated. The process is repeated for the remaining die sizes by changing the core rod inserts. The filling density of the reference cavity is always the highest and is designated 100 for a given sample. This value is decreased with a reduction in wall thickness.

Tests with iron, nickel, copper, tin, and Turkish emery grit indicate that the results are consistent. The powders tested either flowed into the cup or did not enter at all. By evaluating filling densities in different die sizes, the test provides meaningful information in designing tools for a production shop. This test method was used to study blending variables and yielded close agreement with the performance of the production presses. Unfortunately, the test is not simple and requires the use of precise equipment.

Variables Affecting Flow Rate

Flow characteristics are dependent on several variables, including interparticle friction, particle shape and size, type of material, environmental factors, and weight of the bulk.

Characteristics of powder surfaces, such as surface oxide films and lubricant films, also affect flow characteristics. The presence of oxide films on powder particle surfaces alters the friction between particles and increases flow rate. Powders with lower surface oxide contents flow more slowly than powders with higher oxide levels. Minute additions of lubricants may increase the flow rates of metal powder, but further additions will reduce flow rates. For practical purposes, the higher the lubricant level, the slower the Hall flow rate (see Table 6).

In general, reduced flow rates are encountered with powders that exhibit one or more of the following characteristics: low specific gravity, low apparent density, high friction coefficient of fine particles, high specific surface area, a complex blend of different materials, and high moisture content.

Interparticle Friction. The resistance to flow depends primarily on the regions in which one particle hampers the free movement of other particles, either by direct contact or indirectly. This is mainly determined by the coefficient of interparticle friction. Particles may be prevented from moving separately by temporary adherence or interlocking. In this manner, clusters are formed that may occupy considerable volume. The phenomenon of cluster formation depends on the movement and type of powder, the flow varying markedly with the size and structure of the particles. If the particles were all truly spherical, they would generally roll readily into a die cavity. This can rarely be achieved in commercial powders; differences in size and shape are unavoidable.

Particle Size and Shape. Subsieve powders, those with particle sizes less than 44 μm , generally have poor flow rates. For this and other reasons, very fine powders are not used for compacts that are pressed on automatic presses. The particles of most powders used for compacting have irregular equiaxed shape, with flow rates between those of spherical (high flow rates) and flaky (low flow rates) powders.

Type of Material. Flow is influenced by the type of material, whether it be copper, aluminum, or iron. The major influence is the theoretical density. Other characteristics, such as adhesive and cohesive surface properties and magnetic or electrostatic interactions, are also factors.

Environmental Factors. Powders exposed to air containing high relative humidity absorb moisture on particle surfaces, resulting in reduced flow rate. On the other hand, as moisture content increases, many materials tend to agglomerate, which increases permeability and, consequently, increases discharge and settling rates. Seasonal changes in temperature do not affect the flow rate of metal powders considerably. Very low temperatures, however, can cause condensation of moisture; very high temperatures may partially melt the lubricants in the powder mix. Such extreme temperature conditions may cause interruptions in the flow of material through conveying systems. Also, because the permeability factor, K , is inversely proportional to the viscosity of the air or other gas in the void spaces, heating causes the gas to become more viscous, which makes the bulk solid less permeable.

Weight of the Bulk. A metal powder with a lower specific gravity, such as aluminum, generally exhibits slower flow rates compared to high specific gravity powders such as iron. At the same time, the higher the apparent density of a given material, the faster the flow. The ratio of apparent density to specific gravity can be used to correlate the bulk properties of various metal powders.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Sliding at Impact Points

Two key factors in chute design are the chute angle and the smoothness of the chute surface at the point of impact. Too shallow or too rough a surface in a chute impedes flow.

The required minimum chute slope can be determined by placing a ring-type device containing a sample of the powder on a representative sample of the chute wall surface and applying a predetermined vertical load to simulate impact. Once the weight has been removed, the plate is raised to determine the angle at which the particles begin to slide (Ref 23).

All of the factors affecting frictional properties can influence the optimal chute angle, except for time of storage at rest. Because it is uncommon for a chute to remain full without material moving through it, that parameter is generally not a design consideration.

Segregation Tendency

Providing a reliable, uniform mix or blend is critical in producing quality P/M parts. This requires not only proper mixing methods, but also proper handling techniques through compaction to ensure a uniform delivery of the powder to the die. As such, much greater emphasis is now being placed on appropriate storing, feeding, and transporting of powders.

The exact method of die fill depends on the specific compaction process being used (e.g., hydraulic, mechanical, rotary, isostatic, etc.) but generally a feed shoe is used. At the beginning of a compaction cycle, the feed shoe indexes over the die (lower punch) in the fill position and delivers a predetermined amount of powder (sometimes with the assistance of vibration). This is the final and most critical point where variations in the delivered mix directly impact part quality.

Much attention has been given to this specific step in trying to aid in powder filling such that a uniform fill is ensured (Ref 24). However if demixing has already occurred upstream in the process, then the compact will be nonuniform with resulting part-to-part variations. For example, lubricant variations will impact wall friction and subsequent compacting pressures. This, in turn, will cause some variation in compact strength, composition, and density.

Even more critical may be the variation in particle size as it impacts packing behavior and introduces significant density variations. Considering all the other critical variables that affect the compact density and strength (Ref 25) (e.g., compaction pressure, compaction velocities, temperature, wall surface variations and wear, etc.), ensuring that a proper final mix is delivered into the die becomes critical to reducing process complexity and ensuring a high-performance process.

Mechanisms of Powder Segregation. Five mechanisms have been identified as the primary cause of most segregation problems in particulate materials (Ref 26). Of these five, four are known to occur with P/M powders, and each of these mechanisms is described below. The conditions that tend to promote each mechanism are described in Ref 27. Methods to test the tendency for two of the mechanisms to segregate a particular powder blend or mix are also described below. More complete descriptions may be found in Ref 7 and 28.

Sifting. This common phenomenon occurs as smaller particles move through a matrix of larger ones. One of the most likely places in typical P/M processes where sifting segregation can occur is in the filling of a container. For example, during the discharge of the blender (or container) into a portable container (or surge hopper), a concentration of the fine particles will develop under the fill point while the larger particles will tend to roll or slide to the periphery of the pile.

The tendency of a material to segregate by sifting can be determined by running a sifting segregation test. First, a pile is formed under controlled conditions. The pile is then cored to gather a representative sample of particles from its center (under the fill point) and periphery (Fig. 20a). Each cluster is evaluated for particle size distribution, chemical content, and other relevant variables in order to determine the degree of segregation that has occurred. Figure 20(b) shows the results of a sifting segregation test, using a binary mixture.

Fig. 20 Sifting segregation test. (a) Test setup. (a) Test results for binary mixtures

Particle Velocity on a Surface. In general, the frictional drag on particles moving on a chute surface is higher for finer particles than for coarser particles. This results in a velocity difference between the coarse and fine particles, which translates to differences in particle trajectories off the end of a chute. The higher drag of the finer particles along with their position near the chute surface results in a concentration of the finer particles nearer to the end of the chute while the coarser particles come to rest at a much greater distance.

This can become particularly detrimental to the compacting process if portions of the powder stream go to multiple die cavity inlets or if the die cavity provides enough space for this trajectory segregation. In addition, if there are chutes within any of the powder transfer steps, there is the potential for this mechanism to occur.

Air Entrainment (Fluidization). In general, fine or light particles are less permeable than coarse or heavy ones. This allows the finer/lighter particles to retain air longer in their void spaces. Thus, when a mixture of coarse/heavy and fine/light particles is charged into a container or bin, down an empty vertical standpipe, or potentially into the die cavity, the finer particles remain fluidized longer while the coarser particles settle first (sometimes referred to as sedimentation). This results in a vertical segregation pattern within the powder bed.

To determine the likelihood of segregation by air entrainment, a tall cylinder containing a sample of the solid is aerated for a short period (Fig. 21). After the fluidizing air is turned off, sections of the cylinder are removed and the contents of each section are analyzed. If the material has segregated by air entrainment, fines will be located near the top of the cylinder and the coarser or heavier particles will be located at the bottom.

Fig. 21 Fluidization segregation test, (a) Column of material fluidized. (b) Column split and each section measured for segregation

Particle Entrainment. Fine/light particles tend to remain suspended in air longer than coarse/ heavy particles. Thus, for example, air currents can carry airborne fines and light particles away from a fill point to certain areas of a bin, such as toward vents and dust collectors.

Variables that can affect the tendency of particles to segregate include:

- *Particle size distribution and shape:* Sifting segregation is most likely to occur when the material has a range of particle sizes and when there is interparticle motion during operation. Generally, particles greater than about 100 μm in diameter are most susceptible to sifting segregation. If most of the particles are smaller than 100 μm , segregation is more likely to occur by air or particle entrainment.
- *Cohesiveness:* The more cohesive a material, the less likely it is to segregate. Thus, for some materials, the potential for segregation can be reduced by adding binders. In general, this makes the material less free-flowing and causes fine particles to stick to coarse ones. Caution is advised, however, because the additive can rapidly change a situation from one of free flow to one of no flow.
- *Bin flow pattern:* The type of flow pattern that develops can significantly affect the segregation tendency of materials. Typically, funnel flow patterns exacerbate side-to-side segregation (such as that caused by sifting), whereas a mass flow pattern tends to minimize such problems.

Bulk Properties of Powders

John W. Carson and Brian H. Pittenger, Jenike & Johanson, Inc.

Angle of Repose

The angle of repose of an aggregate, or the angle of the surface of an unconstrained pile of solids with the horizontal, is of practical interest rather than of theoretical concern. Of the various physical properties of bulk powders, the angle of repose is the easiest to obtain. It is related to interparticle friction and the flowability of cohesion-less material. This property is frequently used to characterize powdered materials.

The angle of repose of a powdered material does not always give satisfactory reproducibility and is often masked by other factors that are not inherent to the material (most frequently, the presence of a liquid). Thus, before a standard measuring method that provides reasonable reproducibility is developed, its usability as a measure of powdered material property must be established.

However, although the angle of repose is frequently used as a convenient characterization of powdered material, its ultimate reliability depends on the measuring method used. Therefore, the measuring method should be carefully selected, especially when the measured angle of repose is to be used to determine another property, so that it best reflects the property to be quantified.

Measurement Methods

Several methods have been used to measure the angle of repose of materials. Train (Ref 29) studied the angle of repose of a number of grades of glass spheres, lead shot, and silver sand using four different methods, as illustrated in Fig. 22. These methods are:

- *Fixed height cone:* The powder is carefully poured through a funnel at a fixed height until the apex of the heap formed by the powder reaches the tip of the funnel. The tangent of the angle of repose is the ratio of the height to the mean radius of the base of the powder heap.
- *Fixed base cone:* The powder is allowed to flow through a funnel, which is raised vertically until the heap covers a circular base of fixed size. The tangent of the angle of repose is calculated in the same manner as the fixed height cone method.
- *Tilting table:* A rectangular box filled with powder is tilted until the contents begin to slide. The angle that the upper surface of the box makes with the horizontal is equal to the angle of repose.
- *Rotating cylinder:* A sealed hollow cylinder half full of powder is rotated until the surface of powder exhibits its maximum angle with the horizontal. This maximum angle is the angle of repose.

Fig. 22 Four methods used to measure the angle of repose. Source: Ref 30

Brown (Ref 31) reported three methods to measure the drained angle of repose (Fig. 23) and a rotating drum method to measure the dynamic angle of repose, as follows:

- *Ledge:* Material is first charged into a rectangular Perspex box that is 30 cm (12 in.) in height with a 10 by 10 cm (4 by 4 in.) base. A slot at the base of one vertical wall can be closed by a board. The closure board is then removed to allow the material to flow slowly through the narrow slot. The angle with the horizontal of the surface of the material remaining when the flow stops is measured as the angle of repose.
- *Crater:* A circular Perspex tube with a 14.5 cm (5.7 in.) diam is placed vertically on a flat, horizontal base plate having a 1.5 cm (0.59 in.) diam orifice in the center. The powder is discharged through the orifice. The height of the remaining material resting against the wall of the tube is measured at eight equidistant points around the circumference to determine the angle of repose.
- *Circular heap:* A circular platform 7.6 cm (3 in.) in diameter is supported horizontally over a circular hole in a flat base plate and surrounded by a cylindrical tube having 17.8 cm (7 in.) diam and sufficient height (35 cm, or 13.8 in.) to ensure that when it is filled with powder the platform and any heap that may form on it is completely immersed in the powder. The powder in the cylindrical tube is then allowed to flow slowly out of the circular hole in the base plate. The height of the resulting heap on the circular platform is then obtained. The tangent of the angle of repose is calculated as in the fixed height methods.
- *Dynamic angle of repose:* A drum 15 or 30 cm (6 or 12 in.) in diameter and 10.2 cm (4 in.) long with Perspex end faces and roughened internal surfaces is half filled with powder and slowly rotated counterclockwise, with its axis horizontal. Within a certain range of rotation speeds (usually 2.5 to 6 rpm), the surface of the powder in the drum becomes substantially steady. The angle of inclination of the surface to the horizontal is measured at various speeds to determine the angle of repose.

Fig. 23 Apparatus used to measure the drained angle of repose. Source: Ref 30

Table 7 lists the angles of repose measured using these methods. Henein et al. (Ref 32, 33) used a method similar to that used by Brown to determine the dynamic angle of repose and lower angle of repose (shear angle) of several materials. Rotating cylinders of 40 and 106 cm (16 and 42 in.) diam were lined with 24-3 grit type E silicon carbide abrasive paper. One of the two end plates of each cylinder were made of plexiglas to observe and photograph the bed. The maximum angle of bed inclination just before slump occurred was measured with a long-arm protractor, and this angle was designated the upper angle of repose, or the dynamic angle of repose. The angle relative to the horizontal of the shear plane that separated the slumping solids of the bed surface from the material moving with the cylinder wall was considered the lower angle of repose, or shear angle (see Fig. 24). Table 8 summarizes the upper and lower angles of repose of several materials.

Riley et al. (Ref 34) reported methods to measure the angles of repose of cohesive powders. They used both tilting box and fixed bed methods to measure the angle of repose of mixtures of glass ballotini and cohesive powders of different

compositions and then extrapolated the results to obtain the angles of repose of pure cohesive material. Figure 25 shows a sample plot and gives the angle of repose of several cohesive powders.

Factors Affecting Angle of Repose

Internal factors are those inherent to powders, or characteristic of the nature of powders. These include particle size, particle shape, and cohesiveness. In general, larger particles have higher angles of repose. However, very small particles may exhibit cohesiveness due to the electrostatic effect, which increases the angle of repose (Ref 31, 32, 33). Because spherical particles have a greater tendency to roll, they typically have smaller angles of repose than irregularly shaped particles.

External factors are introduced by the environment and may include the method of measurement or the presence of other materials (either solid or liquid). The effect of measuring method is clearly evident as discussed above. In general, the more momentum introduced by the measuring method, the smaller the angle of repose. As a consequence, the drained angle of repose is higher than that obtained from the heap formation method.

The angle of repose of loosely packed dry powder may be increased by compacting, as well as by introducing liquid to the powder. Figure 26 demonstrates the significant effect these factors have on the angle of repose (Ref 30, 35).

Fig. 26 Effect of moisture content on angle of repose of loose and compacted coal. Source: Ref 30

Frydman (Ref 36) reported that the angle of repose of potash pellets may be increased by more than 100% by applying a light spray of moisture to the material surface. The effect of the presence of another solid is shown in Fig. 25.

Compressibility and Compactibility of Metal Powders

Steve Lampman, ASM International

Introduction

COMPRESSIBILITY AND COMPACTIBILITY are terms that define the ability to form "green" (unsintered) compact from the die pressing of powders. In general terms, compressibility is quantified as the amount of compaction pressure that is required to achieve a given green density of a part. A more compressible powder can be compacted to a higher density and, consequently, permits the manufacture of parts possessing higher mechanical properties or the use of a smaller and less expensive compaction press. Thus, compressibility of a powder is a major factor in the design of pressing tools, the part density attainable, and the size of press needed.

Compactibility is a slightly different term related to the green strength of a powder compact, part complexity or fragility, and the ability to eject the compact from the die. For example, with all other factors equal, a simple part has more compactibility than a complex part, because the complex part would require higher ejection force (which increases the likelihood of breakage or cracking). Therefore, in order to increase the compactibility of complex or fragile parts, higher green strength may be needed in order to prevent breakage or cracking during ejection or subsequent handling.

The relation between compressibility and compactibility is complex, because some factors increase one at the expense of the other. In particular, particle shape and particle size are key factors that influence compressibility and compactibility (or green strength) in opposite ways. In terms of particle shape, for example, compressibility is reduced for a mix of irregularly shaped powder, because the particles do not rearrange themselves as easily as they would for spherical shapes. Thus particles with spherical shapes generally have higher compressibility than particles with irregular shapes. In contrast, green strength generally is increased by increasing the particle surface area. This can be achieved by increasing the particle surface roughness and/or reducing the average particle size, thus providing more sites for mechanical interlocking and a stronger compact. Coarse powders reduce the number of contact points between particles, which thus allows particle rearrangement for improved compressibility but also lowers green strength.

However, even though particle size and shape have competing effects on compressibility and green strength, there are factors that enhance both. For example, residual interstitial impurities or solid-solution alloying reduce both compressibility and green strength. This is shown in Fig. 1 for carbon contents of iron powder. Green strength and

compressibility also improve with increased compaction pressure and die temperature as shown in Fig. 2 for a water-atomized iron powder (0.004 wt% C, 0.09 wt% O, 0.05 wt% Mn). Increasing temperature or compacting pressure promotes increased particle movement and deformation, which are the bases for good mechanical interlocking.

Fig. 1 Effect of residual carbon content on compressibility and green strength of water-atomized high-carbon iron powder. Pressed at 550 MPa (40 tsi) with 1% zinc stearate.

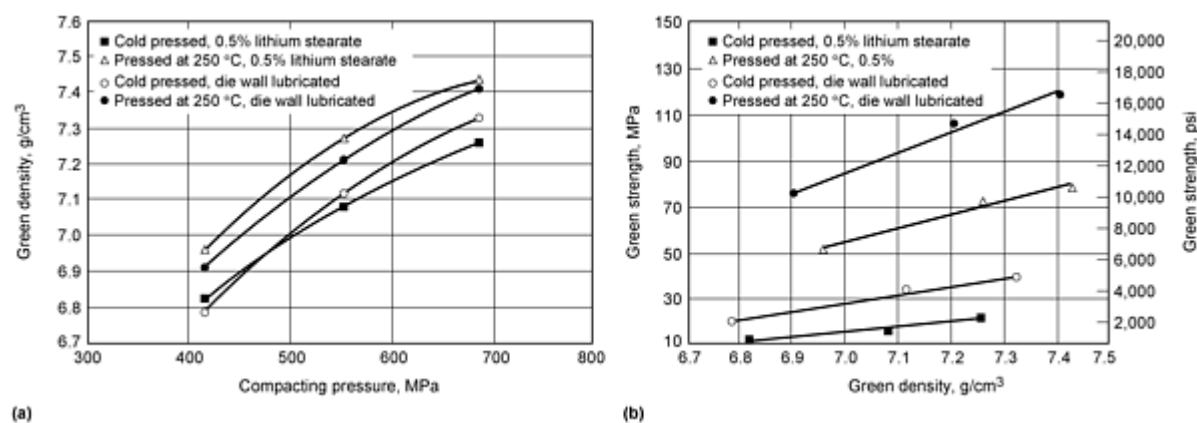

Fig. 2 Effect of compacting pressure and die temperature on (a) green density and (b) green strength of a high purity water atomized iron powder (0.004 wt% C, 0.09 wt% O, 0.05 wt% Mn). Source: Ref 1

Table 1 shows the relationship among green strength, apparent density, compacting pressure, and green density for several types of iron powders. A comparison of compressibility and green strength is also shown in Fig. 3 for two types of iron powder. The powders are close in terms of compressibility (Fig. 3a), but the larger difference in green strength (Fig. 3b) is attributed to more interlocking for the atomized particles.

Compressibility

Compressibility of powders is generally expressed in terms of green density versus compaction pressure. Compressibility is also measured in terms of the *compression ratio*, which is the ratio of final pressed density to the apparent density of the powder.

Typical compressibility data for various kinds of metal powders are given in Fig. 4 as a percentage of theoretical density to demonstrate the relative compressibility of various powders. Because compressibility is so important in the effective and economical production of P/M parts, improvements in compressibility are a significant industry objective (Fig. 5).

Key Variables

Compressibility is determined by several factors including particle shape, density, composition, hardness, and to a lesser extent, particle size. Lubrication and compacting conditions also influence compressibility as described below.

Particle size and shape influence both apparent density and compressibility in a similar way. Small, spherical particles occupy more space than large, irregular ones, and higher compressibility and apparent density is expected for small, spherical particles. This is one reason for the approximate linear relation between compressibility and apparent density (Fig. 6). Highest compressibility is generally achieved with a wide spread in particle size, while powders of a uniform size exhibit relatively poor compressibility. This occurs because mixtures of particle sizes occupy more space and thus have better compressibility and higher apparent density.

Fig. 6 Effect of apparent density on compressibility of iron powders produced by different methods. Compaction at 200, 400, and 600 MPa. Source: Ref 5

Powder Hardness and Oxides. Because considerable deformation of particles occurs during pressing, particle hardness influences compressibility. In addition, some metals tend to work harden more than others. Nonmetallics such as unreduced oxides also reduce compressibility because of their hardness and low specific gravity.

Internal Porosity. Fine internal porosity in a powder tends to become noninterconnected during pressing, thus trapping air within particles. Although air is highly compressible, it takes up volume and contributes little to weight. Nonporous powders have the highest compressibility.

Particle Chemistry. Alloying additions or residual impurities generally degrade compressibility by substitutional or interstitial hardening. For iron powders, substitutional elements such as molybdenum, nickel, and manganese have a much smaller effect on compressibility (Fig. 7) than interstitial elements like carbon (Fig. 1). In particular, nickel and molybdenum produce only small reductions in the compressibility of prealloyed steel powders, while significantly higher compaction pressures are required for chromium, copper, and manganese. The reduction in compressibility from chromium and manganese is attributed not only to solid-solution strengthening, but also to the strong oxidation tendency of chromium and manganese during powder production. Residual oxygen is known to decrease iron powder compressibility as shown in Fig. 8.

Lubricants. The effect of lubricants on compressibility depends on the lubricant and the compaction pressures. Some lubricants perform better than others, but generally lubricants cause a reduction in green strength (Fig. 9). The reduction in compressibility from lubricants is more pronounced at higher compaction pressures (Fig. 10). At higher compaction pressures, lubricants reduce the green density because it occupies the available porosity.

Fig. 9 Effect of lubrication method on green strength. Source: Ref 1

Fig. 10 Effect of lubrication on green density. Source: Ref 1

Lubrication is used to assist ejection of the compacted specimen from the die. Failure to use a lubricant may result in tool seizure and excessive die wear, particularly at high compacting pressures. Common solid lubricants include zinc, stearate, amide wax, and stearic acid.

There are two lubrication techniques. One method is to blend a dry lubricant with the powdered metal. The other method, commonly referred to as die wall lubrication, is to lubricate the die walls and punches of the compacting tooling prior to introducing the powder metal into the die cavity. With the powder lubrication method, the level of lubricant addition may range from 0.5 to 1.5%. With die wall lubrication, the solid lubricant (for example, zinc stearate, 100 g) is mixed with a volatile organic liquid (for example, methylchloroform, 1 L) and is either painted or sprayed on the tooling. The organic liquid evaporates, leaving a thin film of dry lubricant on the working surfaces of the die cavity and punches.

Density of the ejected test specimen varies with the method of lubrication (Fig. 9), as well as with the type and amount of lubricant used. These parameters should be specified when reporting density values that are to be used to determine the compactibility of a metal powder.

Warm compaction of the ferrous P/M parts is a recent innovation that uses heated tooling and powder during the compaction step. The powder and tooling are typically heated between 130 and 150 °C (260 and 300 °F). In order for the powder premix to perform at these temperatures, proprietary lubricant systems have been developed that can withstand the higher die temperatures in warm compaction. Polymer binders in the premix also limit segregation and provide enhanced flow characteristics of the powder premix.

Improved compaction of metal powders (such as aluminum, copper, and iron) at higher temperatures has been used for many years, but the problem with ferrous parts has been that available lubricants for proper ejection could not withstand warm die temperatures. This problem has been solved with improved lubricants (such as the Densmix polymer lubricant first developed and patented by Hoeganaes Corp.), that allow warm compaction. By utilizing warm compaction technology, the green density of the consolidated part can be increased from 0.10 to 0.25 g/cm³ over traditionally processed (single pressed/single sintered) materials. The green strength is typically increased between 50 and 100%. Table 2 compares the green properties of warm compacted and cold compacted P/M parts. This increase in green strength provides advantages such as a reduction in green chipping and cracking due to part handling prior to sintering and makes possible the crack-free compaction of complex multiple-level parts. Additionally, the higher green strength provides an opportunity to machine the P/M part in the green state. This capability is important in the use of high-performance alloys that achieve high hardness in the sintered condition.

Table 2 Effect of processing on the green properties of ferrous compacts

Base material	Processing technique	Compaction pressure		Green density, g/cm ³	Green strength		Peak die ejection force

Annealing of metal powders has become common heat treating practice, because many powder-producing processes yield powders containing residual amounts of carbon, oxygen, and/or nitrogen that reduce green strength and compressibility. Thus, in metal powder production the term "annealing," or the stress relieving and recrystallizing of a cold worked material to increase ductility, includes chemical reactions such as oxygen reduction, decarburization, and denitriding.

Annealing also is used to remove thin surface oxide films from powders that tarnished during prolonged storage or exposure to humidity. Use of annealing for this purpose is more prevalent with relatively noble metal powders such as iron and nickel, which are easier to reduce but which frequently oxidize more readily and completely. Generally, the lower the reduction temperature used to reduce oxide films, the less stable the powder toward reoxidation. Lubrication and/or protective surface treatments improve the stability of powders.

Annealing of Alloy Steel Powders. High-speed tool steel powders require an annealing treatment after atomization. Martensitic and ferritic stainless steels sometimes are annealed in either a nitrogen or dry reducing atmosphere such as hydrogen or dissociated ammonia to improve their compacting properties. Annealing temperatures are kept as low as possible to minimize sintering. Austenitic stainless steel powders are generally used in the as-atomized condition. The effect of annealing on the compressibility (green strength) of 434-L ferritic stainless steel is illustrated in Fig. 11.

Fig. 11 Compactibility (green strength) of ferritic stainless steel 434-L powder in the annealed and unannealed condition

Water-atomized high-speed tool steel powders are annealed either in vacuum or hydrogen. Martensite and retained austenite are thereby transformed to a mixture of ferrite and spheroidal carbide. This renders the powder softer and more ductile and suitable for compaction.

Generally, the annealing treatment for tool steels combines deoxidation and temper annealing. The particles of as-atomized tool steels are as hard as their fully hardened wrought counterparts, with apparent hardnesses in the range of 63 to 65 HRC, which renders the powder virtually impossible to compact, and oxygen levels of ~ 2000 to 4000 mL/m^3 (2000 to 4000 ppm). The annealing treatment reduces the hardness to 23 to 25 HRC and oxygen to ~ 800 to 1000 mL/m^3 (800 to 1000 ppm). A small amount of decarburization is a by-product of annealing.

Compressibility Testing

Standard test methods for compressibility have been issued as:

- ASTM B331, "Compressibility of Metal Powder in Uniaxial Compaction," by the American Society for Testing and Materials
- MPIF 45, "Determination of Compressibility of Metal Powders," by the Metal Powder Industries Federation
- ISO 3927, "Metallic Powders Excluding Powders for Hardmetals--Determination of Compactibility

(Compressibility) in Uniaxial Compression," by the International Standards Organization

Typically, a cylindrical or rectangular test piece is made by pressing powder in a die, with pressure applied simultaneously from top and bottom. The pressure required to achieve a specified density is a measure of compressibility. Compressibility can also be specified as the density achievable at a given pressure. By plotting the density obtained by a series of increasing levels of pressure against these pressures, a compressibility curve is developed.

Two shapes of test pieces have been standardized. One is a cylinder having a diameter of 25 mm (1 in.) and a height of 12.7 to 25 mm (0.5 to 1 in.). The other is a rectangular bar 12.7 mm (0.5 in.) wide by 31.8 mm (1.25 in.) long and 5 to 7 mm (0.2 to 0.3 in.) high. Sufficient powder to form the test bar is loaded into the appropriate die, and a pressing load is applied to the opposing punches. When the specified pressure is reached, the part is ejected from the die and its height and peripheral dimensions measured to determine volume. The weight of the part divided by its volume is a measure of the density achieved at the specified pressure. Alternatively, a given weight of powder is pressed to a predetermined thickness, thus to a specific density. The pressure needed to reach this density is the measure of compressibility.

Tooling used to make these specimens consists of a die, preferably of cemented carbide, or alternatively of tool steel, and two steel punches for producing either cylindrical or rectangular compacts. Exact tool dimensions required for making the cylindrical test piece and the rectangular bar are described in MPIF 45 and ISO 3927.

Compressibility and Compactibility of Metal Powders

Steve Lampman, ASM International

Green Strength

Green strength refers to the mechanical strength of a cold pressed powder compact. Adequate mechanical strength of a green part permits cold pressing of the powder, ejection of the green part from the die, and transfer of the green part to the sintering furnace without breakage. Strength of green compacts results mainly from mechanical interlocking of irregularities on the particle surfaces, which is promoted by plastic deformation during pressing. Figure 12 shows green strengths of various powders versus compaction pressure.

(a)

(b)

Fig. 12 Green strength versus compaction pressure for various types of powder. (a) Copper, iron and steel powders. (b) Iron powders

For most applications, green strength values of about 5.5 MPa (800 psi) or more permit pressing and safe handling of green parts. Lower green strength values may produce insufficient strength and horizontal lamination in the part. These laminations appear when the part is ejected from the die as a result of a small expansion of the part, due to the release of elastic stresses. This type of defect can be minimized or avoided by providing the die with a slight taper (draft angle) or a small radius at the upper rim. Parts with sharp contours or thin sections, or parts made from a blend of several powders in which some of the components detract from the overall strength of the part, require powders with higher green strength characteristics.

Testing for Green Strength

Although metal powder compacts are seldom used in the green condition, green compacts must be strong enough to resist abrasion and breakage while being transferred from a compacting press to a sintering furnace. This is particularly important for thin parts, thin sections of large parts, low-density parts, and part edges. Thus green strength is a key factor that determines the compactibility of powders.

The Rattler test, adapted from a method used to test paving bricks, was used in the early P/M industry to determine green strength. Five compacts of predetermined weight and size were placed in a bronze-screened cylinder and rotated for a certain number of revolutions for a specified time. The compacts were then removed from the cylinder, weighed, and the weight loss determined. The Rattler test provided information on the abrasion resistance of a compact and its ability to retain its shape (edge stability). The Rattler test (MPIF Standard 15-517) is still widely used in Japan.

Transverse Bend Test. Current test methods to determine green strength of an unsintered compact are specified in ASTM B 312 and MPIF 15. The standard green strength test is a transverse bend test of a 12.7 by 31.7 mm (0.50 by 1.25 in.) rectangular specimen 6.35 mm (0.25 in.) thick. A simple rectangular die with an upper and lower punch is needed to produce this transverse-rupture specimen. Prior to pressing the compact, the die wall is lubricated with a mixture of zinc stearate in a solvent. The die is then drained, dried, and filled with the test powder. Alternatively, the powder and lubricant may be mixed prior to compaction.

Comparisons between the two methods are not recommended, because green strength, green density, compressibility, and rupture characteristics vary depending on whether the die or the powder particles are lubricated. ASTM B 312 and MPIF 15 provide all necessary information on test procedures, die dimensions, transverse-rupture test fixture dimensions, transverse-rupture bar dimensions, and required formulations. The term "green strength" in these standards defines the stress calculated from the flexure formula required to break the specimen, and it relates to the resistance of a pressed compact to abrasion and breakage.

Variables Affecting Green Strength

Many theories have been proposed to explain the precise mechanics of green strength. Because the strength of green compacts results mainly from mechanical interlocking of particle surface irregularities, particle shape is the most important factor contributing to green strength. Powders with irregularly shaped particles produce compacts of higher green strength than powders with spherical particle shape. Spherical particles provide the lowest degree of mechanical strength because of low initial surface contact between adjacent particles and a low surface-to-volume ratio.

Generally, green strength is increased by increasing the powder surface area. This can be achieved by increasing the particle surface roughness and/or reducing the average particle size, thus providing more sites for mechanical interlocking. These characteristics also result in decreased apparent density. Figure 13 illustrates the dependence of green strength on apparent density for various iron powders.

Fig. 13 Effect of apparent density and green strength on green strength of various iron powders. Source: Ref 9

Green strength also is increased when oxidation and contamination of particle surfaces are reduced. Optimum mechanical interlocking is impeded when particles are covered with heavy oxide films and adsorbed gases.

Green strength also is affected by other variables such as green density and compressibility. Increasing green density or compacting pressure promotes increased particle movement and deformation, which are the bases for mechanical interlocking. Particle porosity also increases green strength (Fig. 14a), although this also reduces green density (Fig. 14b).

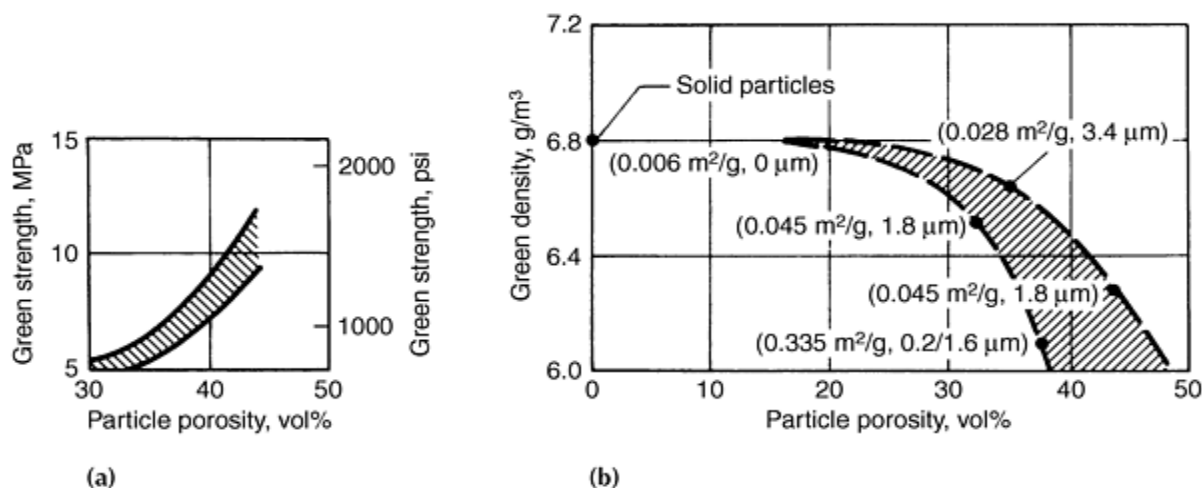

Fig. 14 Effect of internal powder porosity on (a) green strength and (b) green density. Solid and porous iron powders pressed at 414 MPa (30 tsi) using die wall lubrication. Figures in parentheses signify BET-specific surface areas and average intraparticle pore sizes of powders.

Effects of Lubricants. Increasing the amount of additives also decreases green strength. The addition of some alloying elements, such as adding graphite to iron, or the addition of lubricants can reduce the green strength of a compact. Compacts from mixtures of base metal powders and a lubricant generally have considerably lower green strength than those from the powder alone, since the lubricant, which has been added to facilitate ejection from the die wall, does not act as a binder. Instead, the lubricant interferes with particle-to-particle binding. Therefore, green strength tests should be performed on the powder-lubricant mixture as well as on the powder alone.

Table 3 illustrates the effect of a lubricant on green strength and green density of iron and copper compacts. Using a different lubricant, such as an amide wax rather than a metal stearate, can also improve green strength values. Die wall lubrication also improves green strength over that of mixed lubrication (Fig. 15).

Table 3 Effect of lubricant on density and strength of iron and copper compacts pressed at 550 MPa (40 tsi)

Material	Metal stearate lubricant, %	Green density, g/cm ³	Green strength	
			MPa	psi
Reduced iron	None	6.47	32	4600
	1	6.57	23	3300
Electrolytic copper	None	7.97	67	9700
	1	8.11	35	5100

Fig. 15 Effect of admixed lubricant on green strength of water-atomized 4600 low-alloy steel powder

The effect of lubricants on green strength is complex and depends on various factors such as production speed, part size, and lubricant type. Figure 16 and Table 4 illustrate the differences for five different kinds of lubricants. These data are meant to show that different lubricants may help if there are difficulties in the production of green parts.

Table 4 Comparison of lubricants in Fig. 16

Lubricant type	Particle size	Melting point		Ash content, %
		°C	°F	
Ethylenebisstearamide atomized	0.1% +325 mesh	143	289	0.05
Ethylenebisstearamide ground	1% max 100 mesh	143	289	0.05
Ethylenebisstearamide with zinc stearate and stearic acid	0.1% +325 mesh	137	279	1.0
Ethylenebisstearamide	0.5% +325 mesh	140	284	0.05

Green Strength Theories

The two mechanisms used to explain the origin of green strength are cold welding and mechanical interlocking of particles. Cold welding refers to the formation of metallic contacts between neighboring particles during pressing; mechanical interlocking refers to their entangling in the manner of a three-dimensional jigsaw puzzle.

Because both of these mechanisms respond similarly to many powder properties, it is difficult to provide conclusive experimental evidence for either theory. For instance, the important influence of a low apparent density of a powder and the accompanying increase of shearing and heat development during compaction is beneficial to the formation of metallic bonds, as well as to improved keying and interlocking of particles. Nevertheless, some of the features and relationships believed to be specific to each of the two mechanisms are summarized below.

Proponents of the cold welding theory argue that the well-known fact that clean metal surfaces form strong attractive junctions when joined (Ref 11) also applies to the pressing of parts from metal powders. In fact, experimental evidence of such interatomic or metallic bonding forces between powder particles has been presented (Ref 12).

Large and similar reductions in both green strength and electrical conductivity of copper compacts pressed from pure and oleic acid-coated copper powders (Fig. 17) were interpreted to indicate that green strength, like electrical conductivity,

depends on the number and size of metallic microcontacts formed between particles. Thin oxide films on copper powder particles gave similar results (Ref 13).

Fig. 17 Effect of thin film of oleic acid on green strength and electrical conductivity of copper parts

High green strength powders pressed and sintered to the same density as low green strength powders of the same chemical composition produce significantly stronger parts. Because the strength of sintered parts is explainable in terms of metallic bonding and microstructural features, such as grain size and pore structure, and because proportionality exists between green and sintered strength, it is reasonable to assume that bonding forces responsible for strength are identical for both green and sintered parts.

Proponents of the interlocking theory of green strength argue that scanning electron micrographs of fractured surfaces of green parts do not show any evidence of metallic contacts and that parts pressed from spherical powders have no measurable green strength, in spite of substantial deformation and nominal contact areas between particles. Furthermore, roll-compacted green strip has good mechanical strength, yet is quite flexible (Ref 12). Some evidence shows that interlocking may be prevalent at low densities and that cold welding may be dominant at high densities (Ref 13, 14).

The theories on friction welding and interlocking of particles explain the mechanisms responsible for the strength of a green part, but these theories do not permit prediction of green strength from basic powder characteristics. They do, however, provide principles for the development of powders with specific green strength characteristics. The large body of empirical green strength data that is available may be conveniently separated into intrinsic, surface-related, and geometric powder properties (Ref 14).

Intrinsic Powder Properties. Figure 12 shows green strength compacting pressure curves of several metal powders. These curves are typically linear or concave upward (with respect to the pressure axis) and illustrate that green strength increases rapidly with increasing compacting pressure. These curves may be converted into green strength/green density curves by means of the corresponding compressibility (green density/compacting pressure) curves of the powders.

At high compacting pressures or with high-speed compaction, green strength may be lower than expected due to air entrapment during compaction. Such parts may have lamination defects with an appearance similar to those produced by differential expansion during ejection from the die.

In general, green strength increases with the increasing intrinsic softness, or plasticity, of a powder. This relationship is, however, often masked by the influence of geometric powder characteristics. Annealing of a work-hardened powder raises its green strength compacting pressure curve; it may lower its green strength/green density curve, because the annealed powder requires a lower compacting pressure to achieve a given density.

If compaction exceeds the work-hardening capacity of a powder, particle fracture may occur and may cause green strength irregularities.

Surface-Related Factors and Powder Mixtures. The most important commercial examples in this category include the use of mixtures of powders (such as copper and tin or the addition of copper and nickel to iron), the addition of graphite and lubricants, and the presence of oxide films due to tarnishing. The green strength of mixtures of similar metal powders may be estimated from the green strength of its components by applying the rule of mixtures.

The addition of graphite and most lubricants reduces green strength to a much greater extent than indicated by the rule of mixtures, however. The effect of a 1% addition of zinc stearate on the green strength of a water-atomized low-alloy steel powder is shown in Fig. 15. The detrimental effect of the lubricant is more pronounced at high compacting pressures, because it causes the shape of the curve to change from concave to convex.

Because lubricants affect many other powder properties, most notably compressibility and powder flow, selection of amount and type of lubricant addition is made on the basis of the best compromise for a given application. Typically, lubricants that are less detrimental to green strength reduce both powder flow and compressibility.

Most metal powders possess thin oxide films--either directly from manufacturing, as in the case of water-atomized powders, or from subsequent tarnishing in air. The effect of these oxide films on green strength appears to depend on whether these films break down during compaction. For both iron and copper powders, tarnishing or surface oxidation produces significant losses in green strength. Figure 18 illustrates the extent of such losses for copper powder and also shows that oxide films on water-atomized stainless steel powders do not impair green strength. These oxide films were produced by low-temperature oxidation with air in a fluid bed.

Fig. 18 Effect of surface oxide films on green strength of copper and type 316L stainless steel powders

Geometric powder properties include particle shape, particle size, and particle porosity. Spherically shaped solid particles (typical of many gas-atomized powders) have such low green strength that they cannot be used in conventional die compaction. Many water-atomized powders have an irregular particle shape with a solid bulk structure. Such powders typically provide intermediate green strength. Oxide-reduced powders are of irregular particle shape and possess internal particle porosity. Such powders give maximum control over green strength. Green strength increases with increasing particle porosity and with decreasing particle pore size.

Other geometric factors that are beneficial to green strength include decreasing particle size and increasing specific surface area of a powder. Figure 19 shows the effect of particle size for isostatically compacted iron powders. The true effect of particle size is sometimes masked by other factors. Figure 20, for example, shows a maximum for the green strength of a water-atomized steel powder of intermediate particle size. In this instance, particle shape becomes more regular with decreasing particle size; oxygen content also varies with particle size. This is typical of many water-atomized powders. In such cases, the apparent density of a powder is frequently a useful measure of particle shape and green strength. All geometric factors that are beneficial to green strength are detrimental to compressibility.

Fig. 19 Effect of particle size on green strength of isostatically pressed electrolytic iron powder. Fine: 100% - 325 mesh, 90% 10 to 44 μm . Medium: 22% - 325 mesh, 78% - 65 + 325 mesh. Coarse: 100% - 42 + 100 mesh. Source: Ref 16

Powder Shaping and Consolidation Technologies

Introduction

POWDER METALLURGY PARTS are formed by several methods that range from high-pressure die compaction to pressureless shaping methods, such as slip casting. Die compaction at high pressures where densification and shaping occur simultaneously is the dominant approach. However, shaping of P/M products is also accomplished by various low-pressure methods using binders to maintain part shape for further consolidation by sintering. Another alternative is full-density processing, where the application of high pressure at high temperatures leads to P/M components with mechanical properties approaching and sometimes exceeding those of wrought forms. Finally, P/M part technology also includes spray forming of metal powders into high-density parts.

In all of these methods, the basic purpose is to consolidate powders into useful forms. As simple as this sounds, however, shaping and consolidation of powders is a complicated subject. The selection of a shaping/consolidation method involves many decisions, which may include:

- The type of powder to be used (i.e., spherical, sponge, flake)
- The chemistry of the powder (i.e., prealloyed, elemental blend, partially alloyed)
- The use of rigid or flexible tools
- The use of a binder or lubricant
- The use of a directed powder spray to directly consolidate the powder as it is being made

This article briefly introduces and compares powder shaping and consolidation methods, which are described in more detail in subsequent articles of this Section. The emphasis here is to introduce methods for shaping of powder forms and to briefly describe common powder compaction methods, such as those listed in Table 1. The differences between compaction and shaping technologies are determined by many production and application factors, such as part size, desired final density, and shape complexity.

Table 1 Compaction options

Process	Cold isostatic compaction	Cold forging	Die compaction	Explosive compaction	Roll compaction	Warm compaction
Pressure	Moderate, 400 MPa	Very high, >800 MPa	High, 700 MPa	Very high, >1 GPa	Low	High, 700 MPa
Temperature	Ambient	Ambient	Ambient	Very high	Ambient	Warm
Tooling	Soft	Hard	Hard	Soft	Hard	Hard, heated
Deformation rate	Low	High	High	Very high	Low	High
Continuous	No	No	No	No	Yes	No
Pressing direction	3	1	1	1	1	1
Shape complexity	Moderate to high	Moderate	High	Low	Low	Moderate
Polymer level	None	None	Low, 0.5%	None	Low, 0.1%	Low, 0.6%
Precision	Low	Moderate	High	Low	High	High
Use	Moderate	Low	Extensive	Very low	Moderate	Low

Powder Shaping Technologies

General categories of powder shaping methods are as follows (Ref 1):

- Binder-assisted extrusion: long structures, small powders, constant cross section, relatively simple shapes
- Injection molding: complex, small components, high-performance materials
- Slip casting: very large structures, constant wall thickness, low precision
- Tape casting: flat sheets, small powders, very simple shapes

In general these methods employ binders that hold the particles together in the desired shape; the particles are then consolidated to higher densities by sintering. The part is shaped at relatively low pressures (compared to die compaction) with green (unsintered) porosity ranging from ~40 to 60% (ignoring the binder that is sacrificial) (Ref 1). Most binders are polymers such as mineral oil or polyethylene. The following binders are used in powder shaping:

Extrusion

- 56% water, 25% methyl cellulose, 13% glycerine, 6% boric acid
- 72% water, 12% hydroxypropyl methyl cellulose, 8% glycerin, 4% ammonium polyacrylate, 4% ammonium stearate
- 65% polyethylene glycol, 30% polyvinyl butyryl, 5% stearic acid

Injection molding

- 69% paraffin wax, 20% polypropylene, 10% carnauba wax, 1% stearic acid
- 75% peanut oil, 25% polyethylene
- 50% carnauba wax, 50% polyethylene
- 55% paraffin wax, 35% polyethylene, 10% stearic acid

Slip casting

- 96% water, 4% sodium lignosulfonate, trace calcium nitrate
- 93% water, 4% agar, 3% glycerine
- 99% water, 1% ammonium alginate
- 97% water, 3% polyvinyl alcohol

Tape casting

- 77% water, 9% polyacrylate emulsion, 9% glycerin, 3% ammonium polyacrylate, 2% ammonium hydroxide
- 80% toluene, 13% polyethylene glycol, 7% polyvinyl butyral

- 47% mineral spirits, 24% isopropanol, 8% polyvinyl butyral, 8% dibutyl phthalate, 5% polyethylene glycol, 5% stearic acid, 3% menhaden fish oil

In most cases, the shaping process requires four steps:

- Formation of a powder-binder feedstock
- Shaping of feedstock using customized tooling
- Extraction of the binder
- Sintering densification

Feedstock formulation involves small powders and selected binders that are mixed in a ratio dictated by the desired rheology. Shaping may be conducted by several techniques, but powder lubrication by the polymer is key to fabrication of the desired shape. Low-pressure molding concepts, such as slip casting, require an excess of binder. On the other hand, high-pressure shaping is possible with high-viscosity mixtures that contain more powder. If necessary, the polymer viscosity can be controlled by either heat or solvent.

After shaping, the binder is removed (debinding), and the remaining powder structure is sintered. These last two steps can be combined into a single thermal cycle. Since significant shrinkage is associated with sintering densification, the final dimensions rely on uniform shaping to hold tight final tolerances.

Slip Casting. In this method, a low-viscosity slurry (typically from 10 to 50 Pa · s) is prepared with a liquid carrier and powder. The slurry mixture is then poured into a porous mold usually fabricated from plaster of paris. The carrier is evaporated and absorbed into the porous mold, and a free standing shape is thus achieved. In the case of cements, a chemical bond can be created during the drying or curing process. For many powders, sintering is required to achieve particle bonding and to produce a part having useful mechanical properties. This process is more applicable to ceramic powders, and the most popular application is the production of ceramic bathroom fixtures. Slip casting is not commonly used for metal powders. For steels, the largest application is rapid fabrication of prototype shapes and pilot tool steels (Ref 1). Slip casting is very cost effective for large shapes due to inexpensive tooling. More information on this method can be found in the article "Slip Casting of Metals" in this Volume.

Tape casting uses a similar low-viscosity mixture of powder, water, and polymer, but the forming step is via deposit of the mixture on a moving Mylar film. As the water evaporates, the particles are glued together into a thin sheet. It is used to generate homogeneous long, thin, and flat structures, such as sheets. Many of the characteristics of the binder and powder are the same as encountered in slip casting. After forming, the solvent or water is evaporated, leaving residual binder to hold the particles in place.

Tape casting is widely used to form battery electrodes, brazing layers, microelectronic substrates, and small production levels of steel sheets. In tape casting, the powder-binder slurry is fed onto a moving paper or plastic sheet that passes through a controlled opening. A doctor blade levels the slurry to form a continuous thin sheet (Fig. 1). Subsequently, one constituent of the binder is evaporated, leaving bonds of binder behind to provide strength during separation of the tape from the substrate before final sintering. Binders for tape casting are similar to those discussed earlier. Acrylics, waxes, polyvinyl alcohol, and polyvinyl butyryl are common components.

Fig. 1 In tape casting, a thin layer of powder-binder mixture is formed on a moving Mylar substrate, which carries the tape into a drying oven prior to sintering. The technique is used to form thin sheets. Source: Ref 1

Freeze Casting. A novel shaping technique relies on water and freezing to form a shape. The water contains polyvinyl alcohol or latex. After casting into hard tooling, the powder-binder mixture is frozen in the tool set. Subsequently, the ice is extracted by vacuum evaporation (freeze-drying or sublimation) from the compact, leaving behind a polymer component to hold the particles in place for subsequent handling. Sublimation of the water is slow and requires at least a few hours. Finally, the powder is sintered to a high density. The process is known by several names, including adiabatic forming, freeze-firing, and quick set. This freeze-sublime-sinter approach is mostly used for large structures; stainless steel is a preferred material. Current production targets components >1 kg (2.2 lb) in mass with modest production volumes--typically a few per day. This is dictated by the time to freeze the component in the tooling, which limits the cycle time to ~ 1 h.

Injection Molding of Metals and Ceramics. Injection molding is now the most widely employed shaping technique for steel powders. The molding process competes with many other shaping technologies. It overcomes the property limitations inherent in plastics, the shape limitations of traditional powder compaction, the costs of machining, the productivity limits of isostatic pressing and slip casting, and the defect and tolerance limitations of casting.

Part production by injection molding is used with various metals, alloys, and ceramic materials, such as the following (Ref 2):

Elements

- Beryllium
- Copper
- Iron
- Gold
- Molybdenum
- Nickel
- Niobium
- Silver
- Titanium
- Tungsten

Alloys

- Bronze
- Cobalt-base
- Copper-base

- Gold-base
- Hastelloy
- Inconel
- Invar
- Iron-nickel
- Iron-silicon
- Kovar
- Nickel-base
- Niobium-base
- Stainless steel
- Steel
- Stellite
- Sterling silver
- Superalloys
- Tool steel
- Tungsten heavy alloy

Ceramics and compounds

- Alumina (Al_2O_3)
- Alumina-chromia ($\text{Al}_2\text{O}_3\text{-Cr}_2\text{O}_3$)
- Aluminum nitride (AlN)
- Ferrites (MnFe_2O_4)
- Hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$)
- Mullite ($3\text{Al}_2\text{O}_3\text{-2SiO}_2$)
- Nickel aluminide (Ni_3Al)
- Silica (SiO_2)
- Silicon carbide (SiC)
- Silicon nitride (Si_3N_4)
- Spinel (MgAl_2O_4)
- Titania (TiO_2)
- Yttria (Y_2O_3)
- Zirconia (Zr_2O_3)

Cermets and composites

- $\text{Al}_2\text{O}_3\text{-SiC}$
- $\text{Al}_2\text{O}_3\text{-ZrO}_2$
- Mo-Cu
- NbC-Ni
- $\text{Ni}_3\text{Al-Al}_2\text{O}_3$
- $\text{Si}_3\text{N}_4\text{-SiC}$
- $\text{SiO}_2\text{-Si}$
- TiC-Ni-Mo
- W-Cu
- WC-Ni
- WC-TaC-Co
- $\text{ZrO}_2\text{-MgO}$
- $\text{ZrO}_2\text{-Y}_2\text{O}_3$

Noticeably absent are magnesium and aluminum; these reactive metals develop powders with surface oxides that are difficult to remove during sintering. Stainless steel is the most widely used material for injection molded parts, as shown

by the relative ranking in Fig. 2. Stainless steel 316L is the most commonly used alloy. Ferritic and duplex stainless steels are also used.

Fig. 2 Relative material utilization in powder injection molding (PIM) processing on a weight basis, showing the dominant position of steels and stainless steels. Source: Ref 2

Injection molding moved quickly from a laboratory development to a commercial process for two reasons. First, a precision shape could be achieved at a significant cost reduction compared to a conventional manufacturing process. Second, the use of fine powders promoted densification during sintering, and high properties could be achieved. The high potential of the process added a third reason that sustained growth. Availability of fine powders and pellet feedstock from suppliers increased as the process showed early successes. There is still a great deal of development work toward more efficient and economical production of fine powders ($<20\ \mu\text{m}$) specifically to supply the injection molding industry.

In the as-molded state, the green part is typically $\sim 65\ \text{vol}\%$ powder and $\sim 35\ \text{vol}\%$ binder. Therefore, upon removal of the binder, considerable densification is required to achieve density levels of ~ 95 to 98% of full density. This densification must be accompanied strictly by size change because unwanted shape distortion would render the part useless. Therefore, uniform particle distribution in the binder is essential. Also, to minimize contamination, the binder must either be removed completely before sintering, or it must participate in alloying during sintering.

A binder/plasticizer has also been used to extrude long shapes rather than just mold individual shapes. A heated barrel plasticizes the binder, and a die gives shape to the powder being extruded. With this technique it is possible to form fluted shapes, hollow tubes, tubes with multiple cavities, and other complex shapes. More information is in the article "Powder Injection Molding" in this Volume.

Rapid prototyping technology includes quick methods for making templates, models of parts, prototype molds and dies, and fully functional components. Rapid prototyping methods rely on variants of powder metallurgy capabilities such as selective sintering, powder spraying, ink jet techniques for directed spraying, and deposition. Several methods are discussed in the article "Powder Metallurgy Methods for Rapid Prototyping" in this Volume.

Powder Compaction Methods

Powders are compacted under high pressure by various methods (Table 1) where the application of pressure packs the powders and reduces porosity. Unlike shaping methods, compaction techniques cause particle deformation. Many compaction methods are used, but the most prevalent method for P/M parts production is uniaxial compaction in a rigid die. This method is cost effective with relatively straightforward tooling.

However, compaction methods inherently produce parts with density variations that result in dimensional variations of the final sintered part. This occurs because the transmittal of stress through a mass of powder particles is not uniform, even in isostatic pressing. In the case of compaction in a rigid die, the uniformity of stress transmitted through the powder mass and the density distribution in the green compacts produced in rigid dies are much less uniform than in isostatic compacting. This can be understood by considering flow around corners. When a liquid is subjected to hydrostatic pressure inside a confined, rigid die, the stress transmitted by the liquid upon the interior surfaces of the die is uniform, regardless of whether the liquid must flow around corners. This is not so when a powder is pressed; it flows only in the direction of the applied pressure and not around corners. This phenomenon is illustrated in Fig. 3, which schematically shows the compaction of powder in a die with a sidearm. If pressure is applied only to the top punch, the powder is compacted only in the vertical section of the die, but remains loose in the horizontal section. Compaction in the sidearm is obtained when pressure is applied to both the top punch and the side punch.

Fig. 3 Density distribution of compacts pressed in dies with a sidearm

Uniaxial Die Compaction

In uniaxial compaction of metal powder, pressure is applied to the powder only with punches that move in the vertical direction. Compacting metal powder parts in rigid dies, where the punches move only in the vertical direction, imposes limitations on the shape of the parts that can be readily produced. Parts with re-entrant angles and with holes at an angle to the vertical direction generally are not produced by compacting.

Another consequence of powder flowing only in the direction of the applied pressure during compaction is that, when parts with different levels of thickness in the direction of pressing are compacted with only a single lower punch, they develop different green densities in the different levels. Individual punches for each level are necessary for a more uniform density. These punches must travel in such a way that the ratio of the height of the loose powder to that in the green compact (the compression ratio) is the same for all levels. This type of punch arrangement is illustrated in Fig. 4. Pressing from both top and bottom also reduces density variations (Fig. 5).

Fig. 4 Density distribution in a two-level compact

Fig. 5 Density distribution in compacts

Even compacts with only one level in the direction of pressing show variation in density in the pressing direction due to the friction between the die wall and the powder. This friction is reduced as much as possible by lubricants. Usually, lubricants are added to the metal powder in powder form. Lubricants reduce friction between the powder and the side wall, as well as between individual powder particles. They also may be applied as a thin coating to the walls of rigid dies. In large-scale production, this die wall lubrication is not commonly used.

Mathematical relationships and modeling of pressure-density relationships in powder compaction have important practical value, especially with greater emphasis on concurrent engineering. Modeling of compaction is discussed in the article "Mechanical Behavior of Metal Powders and Powder Compaction Modeling" in this Volume.

Cold pressing in rigid dies is the most commonly used compaction process, and the concept of die pressing is straightforward. Powder is poured into a die cavity, a movable punch seals the die cavity, and a load is then applied via the advancing punch. In the most simple case there is only one moving punch, and the die is stationary. However, a density gradient in the compact occurs as a consequence of die wall friction, with the highest density being next to the punch face. A floating die table reduces the density gradient by moving the die to offset the friction effect. The powder is densified from both top and bottom planes, and the middle plane has the lowest density. As more features are added to the compact, additional punches are required to produce an acceptable green compact.

Typical green densities for die compacted parts are 75 to 85% of full density. Green density is related almost exponentially to the applied load. At low densities, a small increase in load causes a major increase in density, while at high density levels, a large increase in applied load is required to get a small increase in density. The required compaction pressure to achieve a desired level of density is a function of the following:

- The powder shape (i.e., sponge, flake, water atomized, reduced)
- Particle size and size distribution
- Powder chemistry (i.e., prealloyed, blended master alloy)
- Lubrication practice

For steel powders, commonly used pressures are in the 400 MPa (30 tsi) range to achieve green densities from 80 to 85% of full density. The use of "low compressibility" powders, which truly do require less pressure to achieve the same density as prealloyed powders, allows either larger parts to be made on the same pressing equipment, or parts with higher green density to be made at the same compaction pressure. More information on compressibility is provided in the article "Compressibility and Compactibility" in this Volume.

Cold pressing in rigid dies has advantages of dimensional control due to the well defined cavity, high compaction pressures due to mechanical or hydraulic pressing equipment, process repeatability due to mechanization and improved powder consistency on a batch-to-batch basis, and high rates of production. Limitations of the process include size restrictions due to press capacity, height-to-diameter limitations due to die wall friction, ejection cracking problems with compacts pressed from powders with poor green strength, and the natural limitations of re-entrant angles and undercuts. Creative toolmakers circumvent or overcome these limitations daily.

Warm compaction is a rather recent development in production die pressing. In warm compaction, a plasticizer is added to the powder whereby the application of moderate temperatures causes the plasticizer to soften or melt and friction is substantially reduced. Friction here refers to friction between the powder and the rigid die wall and to friction between powder particles. With this process, significantly higher green densities can be achieved, even >92% of full density. This technology opens new applications to pressed and sintered parts because of the achievable density and the improved mechanical and physical properties. In addition, higher green strengths allow machining of green compacts.

Usually warm compaction involves the use of a polymer addition that helps bond particles together. The polymer-coated powder is more costly than typical die-compaction grades, unless a simple lubricant is admixed with the powder. Various common stearates or other lubricants work, including, Teflon (E.I., duPont de Nemours & Co., Inc., Wilmington, DE). Depending on which polymer is selected for coating the powder, ejection forces can be highly variable. Close temperature control is necessary, since product uniformity suffers if the polymer is too hot. In tests with various powders, the green density usually increases by 0.15 g/cm³ over room-temperature compaction. After cooling to room temperature, the warm-compacted powder is stronger because chilling the polymer adds strength to the compact. However, there is no evidence of greater strength during ejection, which means that green cracks from ejection stresses are not reduced by warm compaction. Consequently, a hold-down pressure is required during ejection to avoid cracking.

Heating of the die and punches requires modifications to the compaction press, and a heater is required in the powder feed mechanism. Both microwave and hot-oil heaters are available for heating the powder. A typical temperature for the powder and tooling is ~150 °C (300 °F), and compaction pressures are usually in the range of 700 MPa (50 tsi) for steels. The major role of warm compaction is to lower the pressure required for attaining densities of >7.0 g/cm³ of ferrous P/M compacts.

Hot Pressing. The production of large billets can be accomplished by compacting powder in heated dies. The use of elevated temperatures and long dwell times allows densities of >95% of full density to be achieved at compaction pressures that are one third to one half those needed for cold pressing to lower density levels. Full density is usually not achieved, and 3 to 5% porosity remains in the billet. This porosity somewhat limits the use of hot pressed billets because the properties are reduced from those of fully dense material. For this reason hot pressed billets are often used as stock for upset forging, closed die forging, and other deformation processes that can eliminate this residual porosity. Some metals, such as beryllium, are routinely processed by hot pressing, and acceptable performance levels for many applications are achieved.

Isostatic Pressing

Isostatic pressing allows more uniform density compared to uniaxial compaction in rigid dies. These methods rely on flexible molds for application of pressure in all directions, which reduces friction and allows compaction of compact shapes.

Cold Isostatic Pressing. CIP uses a flexible membrane to isolate the powder from a liquid medium that is pressurized to cause densification of the powder. Typical mold materials are latex, neoprene, urethane, polyvinyl chloride, and other elastomeric compounds. Because the mold moves with the powder as it densifies, friction effects are minimized. Also, because the pressure is applied uniformly around the mold, there is no theoretical size limit. Height-to-diameter and overall size are limited by the pressure vessel size. Often a rigid mandrel is part of the tooling; and, because powder must slide along this mandrel, it is coated with a friction reducing material.

In comparison to die pressing, cold isostatic pressing can achieve more uniform densities due to minimized friction effects. Pressure vessels are typically limited to pressures of 415 MPa (60 ksi) although units with twice this capacity have been produced. Isostatic pressing equipment can be automated (i.e., dry bag CIP units), but the production rates are lower than those of die pressing. Dimensional control is generally not as tight as with die pressing due to flexible tooling. As stated, however, rigid members can be incorporated into the flexible mold assembly to produce accurate surfaces where desired.

Hot isostatic pressing (HIP) is a versatile near-net shape process that has found niches in the production of aerospace structure and engine markets, high alloy and tool steel mill shapes and individual components, titanium hardware, and monolithic and composite alloy components for the energy industry. The process fundamentals and manufacturing steps are covered in detail in the article "Hot Isostatic Pressing of Metal Powders" in this Volume.

The aim of hot isostatic pressing is a near-net shape and full density. Powder is hermetically sealed in a container that is flexible at elevated temperatures; the "canned" powder is heated within a pressurized vessel and held for a specified time. Commercially used containers include low carbon steel sheet formed into a container, stainless steel sheet, and even glass. The pressurized medium is usually an inert gas such as argon, and pressures range between 100 and 300 MPa (15 and 45 ksi). The temperature for HIP is material dependent, of course, but typical production equipment can heat parts ~ 1000 to $1200\text{ }^{\circ}\text{C}$ (2000 to $2200\text{ }^{\circ}\text{F}$). HIP units for ceramics and carbon-base materials may heat up to $1500\text{ }^{\circ}\text{C}$ ($2700\text{ }^{\circ}\text{F}$). Densification mechanisms active during HIP include bulk deformation (limited amount), sintering, and creep, with the latter accounting for a significant portion of densification. Densities $>98\%$ of full density are typical, and full density is routinely achievable with care during powder sealing and strict control of time, pressure, and temperature.

The powders used in hot isostatic pressing are usually spherical in shape and very clean. The particle surfaces are free of contaminants, such as oxide films. The sphericity facilitates can loading and handling, and the particle surface cleanliness facilitates particle bonding. Powder handling and avoidance of contamination is critical to the success of the process, and considerable investment in facilities and equipment, followed up by attention to operating procedures and "good housekeeping," is required.

In comparison to hot pressing where only billet shapes are produced, hot isostatic pressing is capable of producing complex shapes. As in cold isostatic pressing, the achievable dimensional tolerances are at best near-net due to the flexible mold. Some net surfaces may be achieved if rigid members are incorporated into the mold. Figure 6 compares HIP capabilities with other compaction methods.

Fig. 6 Application areas of HIP based on part size, complexity, and level of densification three variables that dictate the P/M approach are size, density, and performance (as a percentage of wrought). This behavior corresponds to ferrous-base P/M systems, but is representative of many P/M materials. P/S, press and sinter; reP, press, sinter and repress; P/S + F, press and sinter and forge; CIP + S, cold isostatically press and sinter; HIP, hot isostatic press; HIP + F, hot isostatic press plus forge.

Powder Shaping and Consolidation Technologies

Bulk Deformation Processes

Powder Forging. In powder forging, a preform shape is cold pressed to between 75 and 85% of full density, sintered, heated to a forging temperature, and then forged in trapped dies using one blow to produce a fully dense net or near-net shape. The sintering step is optional, but it is normally included as a particle surface cleaning step (deoxidation) and to improve the workability of the porous preform. Powder forging fundamentals and general applications are presented in the article "Powder Forging and Hot Pressing" in this Volume. More detailed information is also contained in the article "Powder Forged Steel."

Normally, powder forging is performed hot (1000 to 1200 °C, or 1800 to 2200 °F, for steel powders), but it can also be conducted at warm or cold forging temperatures. Typical steel powder forging pressures are 550 to 950 MPa (40 to 70 tsi). Because the workability of a porous preform is poor, the design of the preform is critical to the process in terms of avoiding defects. Local surface tensile stresses and internal hydrostatic tension must be avoided. Nonetheless, with a correct preform shape and a well controlled process, powder forged parts have sound microstructures, good hardenability, and performance that meets or exceeds cast-wrought part performance.

There are two classes of forging practice. In repressing, the preform shape is nearly identical to the forged shape. In true forging, considerable shear deformation is involved since the preform is different in shape from the forging. The dynamic properties of toughness and fatigue resistance are higher for forged parts than for repressed parts.

Powder Extrusion. Loose powder can be containerized and extruded to full density, either with or without heat. Extrusion ratios of at least 9:1 have been shown to produce full density, and many materials are extruded to full density using much higher extrusion ratios. Extrusion at such high reductions subjects the powder particles to high levels of shear deformation and compression as they pass through the die. The result is sound particle bonding. As in hot isostatic pressing, the powder is usually hermetically sealed in a container prior to extrusion. In some alloy systems, residual air provides oxygen for selection oxidation of alloy ingredients prior to extrusion, and an oxide dispersion strengthened material is produced. In some other cases, particulates or chopped fibers may be added to the matrix powder, and extrusion produces a composite material. In still other cases, combinations of powders or powder plus wrought pieces are

extruded to produce multimetal parts, e.g., bimetallic tubing. These and other uses of extrusion are discussed in the article "Extrusion of Metal Powders" in this Volume.

Powder rolling or roll compaction of powders consolidates loose powder(s) into a porous strip as it passes through a roll gap. It is possible to produce a monolithic strip or a multilayer strip. Further processing may include sintering of the strip and additional rolling to densify the strip. Applications of this type of processing include such diverse products as clad metal for coin stock, automotive sleeve bearings, and electrode stock.

Powder Shaping and Consolidation Technologies

Sintering

For sintering to be effective, the powder particles must be in intimate contact. For this reason, sintering is typically performed on compacted or molded powder and not on loose powder. While most powder parts are sintered during their manufacture, the densification stage of sintering may not be utilized, and in these cases the primary use of sintering is to achieve metallurgical bonding of particles. Die pressed parts typically fall into this category because dimensional control is of primary importance.

Process routings that rely on sintering specifically to achieve high densities usually fall into three categories. A very fine particle size is used so that bulk diffusion paths are minimized at the last stage of sintering, and there is a high initial surface area to drive sintering in its early stages. This is one reason for the use of ultrafine powders in injection molding where sintering is the primary mechanism for development of high property levels. A liquid phase, either permanent or transient, is present during sintering so that particle rearrangement is promoted. A high temperature is used so that local melting may accompany sintering.

Liquid Phase Sintering. The use of blended powders allows the combination of a low melting powder with a higher melting powder so that a liquid is present during sintering. This liquid can aid powder rearrangement and densification of a green compact. Cermets are typically produced by this technique. Nearly pore-free microstructures may be achieved by this technique.

Transient Liquid Phase Sintering. A subclass of liquid phase sintering is transient liquid phase sintering. Here, a blend of powders contains a lower melting point phase, as above. Only in this case, the liquid alloys with the solid phase which remains solid, and the liquid is present only for a brief period. This process is not used as the primary densification method, but it is used to achieve another increment in density. For example, it may be used in high alloy steel or tool steel production to increase the density of a green compact from 80% to >95% of full density.

High-Temperature Sintering. If the temperature of the green compact is raised to levels very close to the solidus temperature of the equilibrium diagram, small pools of liquid can form due to microsegregation of alloying elements. This small amount of liquid accelerates densification during sintering. Although this represents a somewhat extreme use of high temperature sintering, this technique is useful for a wide range of alloys, and it is used especially for tool steels and other high alloy steel components. The article "High-Temperature Sintering of Ferrous Powder Metallurgy Components" in this Volume contains more information on high-temperature sintering.

Reactive Sintering. By taking advantage of the flexibility of powder metallurgy, a blend of powders may be compacted and then sintered so that during sintering a self propagating reaction occurs (see "Combustion Synthesis of Advanced Materials" in this Volume). This reaction, if controlled properly, can densify the compact rapidly while forming the new alloy. If not controlled, the component may revert to powder!

Compaction to Higher Density

Many methods have been investigated and developed for pressing metal powders to higher densities. Most of the commercial methods involve high-temperature compaction (such as hot isostatic pressing and powder forging, as described in detail in other articles in this Section). In general, these methods are used to develop fully dense or nearly fully dense P/M products. For example, conditions for full-density iron and steel by HIP are summarized in Table 2.

Table 2 Hot isostatic pressing conditions for full-density iron and steel

Material	Pressure, MPa	Temperature, °C	Time, h
4 μm carbonyl iron	200	805	1
75 μm sponge iron	98	1000	1
70 μm low-alloy steel	150	800	1
190 μm maraging steel	210	1200	3
100 μm austenitic stainless steel	160	1150	3
120 μm martensitic stainless steel	150	1150	3
65 μm Fe-10Al-5Si	200	1000	1
80 μm tool steel	100	1100	1
165 μm iron superalloy	69	1200	3

Source: Ref 1

However, other methods besides high-temperature compaction are used to achieve higher densities in green or consolidated form. Some of these miscellaneous methods are described here. These methods are not necessarily full-density methods, and none have reached any significant commercial significance. They are described for general reference. Many experiments also have been reported that attempt to press compacts to higher densities or to produce a more uniform density and stress distribution in pressed compacts. Although none of the techniques developed has led to large-scale industrial use, they are discussed here.

Die Barrel Rotation. Rotating the die barrel while the powder is being pressed using a fine atomized aluminum powder was reported by Hammond and Schwartz (Ref 3). They lubricated the die barrel with a suspension of lithium stearate in didecyl alcohol. Annular compacts, 12.7 mm ($\frac{1}{2}$ in.) high, were pressed with outer diameters of 38 mm ($1\frac{1}{2}$ in.) and inner diameters of 25 mm (1 in.). The core rod was stationary, but the die barrel could be rotated during compression.

Compaction with a stationary and a rotating die barrel was compared. While in static compression, 20% of the applied stress was consumed in die wall friction, while only 2% of the stress was consumed when the die barrel was-rotated. In addition, the pressure necessary to eject the compact from the die was reduced to approximately one half of the pressure for compacts pressed with a stationary die barrel. Similar experiments on the effect of die barrel rotation on the density of iron powder compacts were reported by Rutkowski et al. (Ref 4).

Triaxial compression by simultaneous isostatic and uniaxial compression is obtained by applying pressure to the circumference of a cylindrical specimen confined in a flexible envelope while an axial load is superimposed by a vertical piston. With this method, the level of pressure necessary to obtain a given density is less than with isostatic or uniaxial compression alone. For example, to compact an atomized iron powder (Ancor 1000) to a relative density of 85%, uniaxial compression at 540 MPa (78 ksi) or isostatic compression at 415 MPa (60 ksi) is necessary. The same density can be obtained by combining a confining (isostatic) pressure of 83 MPa (12 ksi) with a uniaxial pressure of 470 MPa (68 ksi). The principles involved in this method of compaction have been reviewed by Broese van Groenou (Ref 5).

High-Energy-Rate Compacting. The rate at which pressure is applied in compacting in a hydraulic press is slow. Compacting in certain mechanical presses is somewhat faster. The effects of the rate of pressure application in compacting were studied by Davies and Elwakil (Ref 6). They found that somewhat higher densities can be obtained for a given pressure and for a given energy input when compacts from iron powder are pressed in high-speed presses (petro-forge-presses). They also determined the effects of multiple blows during pressing.

In the fabrication of sheet metal products, techniques were developed that formed sheet metal at rates considerably higher than those obtained in fast-acting mechanical presses. This is the high-energy-rate forming technique, which generally uses explosives (see also Ref 1).

The success of high-energy-rate forming in fabricating sheet metal led to extensive experimental work on high-energy compacting of metal-powders. The most common means to achieve high velocity is by the use of explosives. In one experiment, for example, compaction was done in a rigid die with pressure applied by a projectile propelled by an explosive charge that moves through a barrel (Ref 7). In a similar experiment compressed gas actuated the projectile (Ref 8). This experiment showed that the density of copper powder is not so much a function of projectile velocity, but depends primarily on the kinetic energy of the projectile, which can be varied by proper selection of gas pressure and projectile mass (Ref 8). For copper compacts with a volume of 0.86 cm^3 (0.052 in.^3), relative densities of $\geq 95\%$ were obtained with energies of 150 J ($110 \text{ ft} \cdot \text{lb}$).

The most widely used method of explosive compacting is shown schematically in Fig. 7. The powder to be compacted is placed in a steel tube, which is closed at each end by steel plugs. The steel tube is surrounded by an explosive that is set off by a detonator located so that on detonation the tube collapses uniformly inward. Experiments by Lennon et al. (Ref 9) showed that density is a function of energy. They developed the equation:

$$D_c = D_T - \Delta D^{-(\beta E^\gamma)}$$

where D_c is the compacted density, D_T is the full density of the material, ΔD is the difference between full and compacted density, β and γ are constants, and E is the net energy absorbed by the powder. The highest relative densities obtained for iron, nickel, copper, and aluminum powders and the corresponding net energies absorbed per unit volume of compact in their experiments were:

Powder	Density ^(a) , %	Net energy, J/cm ³
Iron	98.1	261
Nickel	98.1	556
Copper	98.5	285
Aluminum	99.0	182

(a) Percent of theoretical density

This method of explosive compacting is not necessarily confined to cylindrical compacts. Cones and hollow cylinders have also been explosively compacted by this technique (Ref 10).

Fig. 7 Explosive compacting with powder contained in a steel tube

Vibratory Compacting of Powders. Vibration can be very effective in obtaining higher packed densities in powders. The relative densities of powders vibrated under carefully controlled conditions are much higher than those obtained by simply pouring the powder into the container. Therefore, much lower compaction pressures are required to reach a given density for a vibrated powder than for a poured powder. This is illustrated in Fig. 8 for a carbonyl iron powder. The density of 5.53 g/cm^3 (71% relative density), reached by compacting under a pressure of 245 MPa (35 ksi), is due to the plastic deformation of the iron powder particles, while the 5.37 g/cm^3 (69% relative density) obtained by vibrating at 167 oscillations per second is due mainly to vibratory packing. Plastic deformation during the simultaneous compacting at 2.4 MPa (0.36 ksi) is minimal. The method of consolidating powders by vibrating and simultaneous compacting is, therefore, primarily applicable to hard powders, such as refractory metal and cemented carbide powders, which can be densified relatively little by pressure application alone.

Fig. 8 Effect of powder vibration on densities of carbonyl iron compacts. ○ Obtained in static pressing. • Vibratory compacting at a frequency of 233 oscillations per second. □ Vibratory compacting at a frequency of 167 oscillations per second

Melt-spray deposition of powders encompasses a wide variety of materials and product forms. It can be used to produce monolithic shapes by build up of the spray deposition, or it can be used to form coatings by deposition of a thin layer. One of the largest applications for melt-spray deposition is welding, including hardfacing and plasma spraying techniques for coatings.

Spray forming is also a method for producing preforms by a buildup of sprayed metal powder. These preforms and billets subsequently can be consolidated into various mill shapes. Of these processes, the Osprey process, developed in Wales by Osprey Metals Ltd., and the controlled spray deposition process are in commercial use. Several other methods are being developed; plasma spray buildup has high commercial potential. Laser techniques, such as laser glazing, also have commercial potential, especially when combined with rapid solidification technologies.

Osprey Process. Facilities for production of preforms made by the Osprey process consist of induction melting equipment and a preform production unit. In the Osprey process, an alloy is melted and subjected to gas atomization under inert conditions (usually nitrogen or argon is used). The atomized droplets are collected in a mold or group of molds, in which final solidification occurs. Molds are normally copper cooled by water. High-temperature ceramics offer

other material options for molds. During solidification, welding of particles causes buildup of alloy in the mold. A preform having a density >96%, and normally >99%, of theoretical is generated by this buildup of alloy. The preform then can be consolidated to full density and formed into a mill or near-net shape part.

Alloys that have been processed by the Osprey process include stainless steels, high-speed steels, and nickel-base superalloys, although many materials appear to be compatible with the process. Alloy development has centered on high-alloy ferrous metals, Stellite alloys, superalloys, and composite materials. Because an inert atmosphere is maintained during spraying, oxygen levels similar to conventional ingot metallurgy products are attained, typically 20 to 40 ppm for superalloys. The high preform density ensures that no interconnected porosity is present in the preform, preventing internal oxidation during transfer of the material to subsequent consolidation and forming operations.

The Osprey process is used to produce a wide variety of preform shapes and sizes. Typical preform shapes are tubes, rings, cylinders, disks, or simple billets. Size is dictated by economics, with the melt facility, atomizer, and inert chamber sized for a particular product line. The largest preform size produced weighed 540 kg (1200 lb). Typical deposition rates range from 10 to 90 kg/min (20 to 200 lb/min). More information on the process is described in the article "Spray Forming" in this Volume.

The controlled spray deposition process is similar to the Osprey process in principle, but uses different machinery. Controlled spray deposition uses centrifugal atomization, while the Osprey process involves gas atomization. This process is used for production of mill shapes from high-alloy steel, which utilizes the enhanced workability of P/M workpieces. Highly alloyed metals may suffer from macrosegregation, which reduces the material workability. Elimination of segregation on a macroscale, coupled with a uniform distribution of fine carbides (2 to 3 μm range for M-2 high-speed steel), results in improved workability for P/M workpieces produced by spray deposition. These billets are processed subsequently into mill shapes and sheet products.

By atomizing liquid metal into droplets 0.5 to 1.5 mm (0.02 to 0.06 in.) in diameter, solidification rates three or more orders of magnitude higher than those of conventional ingot solidification are achieved. Impacting liquid droplets of metal onto a cooled substrate increases the solidification rate, resulting in solidification rates of 10,000 to 1,000,000 $^{\circ}\text{C/s}$ (18,000 to 1,800,000 $^{\circ}\text{F/s}$). Controlled spray deposition relies on this type of splat solidification to build up a solidified deposit that becomes a workpiece for subsequent deformation processing. As the thickness and temperature of the built-up material increases, the solidification rate decreases, but it remains much higher than that of conventional ingot solidification. Heating prior to hot working can remove any microstructural variations that may exist throughout the thickness of the built-up deposit.

Along with the metallurgical benefits of controlled spray deposition, economic advantages of direct spraying of powder into preform shapes are attained by eliminating sieving, blending, and other powder preparation steps. Also, primary compaction of powder into a green shape is eliminated. Controlled spray deposition proponents claim that these reductions in equipment needs and processing steps allow more efficient utilization of energy, compared to conventional pressing and sintering P/M technology.

Selecting a Process

Selecting the proper process for consolidating powder to produce a part requires making many decisions. Using the performance requirements as the accept-reject criteria, the wide range of possible processes can be narrowed down, but usually the designer/manufacturer still finds that several methods are possible for producing a particular part. The final selection is then usually based on the availability of equipment, the experience with particular processes, and the marketplace requirements of cost, delivery, and quantity.

Some guidelines and corollaries to these guidelines are presented here as an example of process selection decision making. These are not hard-and-fast rules for several reasons. First, the craft or skill aspect of parts making will alter these guidelines for each and every company. Second, new methods, new powders, and new equipment constantly require that any such set of guidelines be adjusted. Third, the marketplace itself dictates changes and additions to such guidelines. The reader is encouraged to take these guidelines and corollaries as a starting point, then modify and add new statements with quantified details wherever possible so that the decision making process within each organization is captured.

Guideline 1: Control of porosity is the most important aspect of a consolidation process. The size, shape, distribution, and volume fraction of pores is the singlemost important property of a powder metallurgy part. The performance of the part is directly dependent on these aspects of porosity. Therefore, the partmaker must control porosity in order to achieve a usable part, and the consolidation process is critical to controlling part porosity.

Corollary: Dynamic properties such as toughness and fatigue resistance improve dramatically as porosity is eliminated. Higher part stresses during application require higher densities. If a powder metallurgy part must compete with a wrought part, full density must be achieved in all critically stressed regions. This is especially true for applications that require high toughness or where cyclic loading is a life limiting condition.

Guideline 2a: Control of dimensions is the second most important aspect of the consolidation process. The successful implementation of parts production using powder metallurgy techniques is due to the minimization or elimination of machining operations. Therefore, the consolidation process must offer substantial control of the final part dimensions so that secondary operations are minimal.

Corollary: The use of rigid tooling provides superior control of dimensions in comparison to flexible tooling. Therefore, die pressing, injection molding, and powder forging are preferred over cold and hot isostatic pressing in terms of dimensional control. The shape of specific sections of isostatically pressed components can be better controlled by the selective use of rigid fixtures such as mandrels or pressing plates.

Corollary: The effect of friction on porosity distribution must be taken into account in order to maintain control of dimensions. Porosity gradients due to friction can cause nonuniform dimensional change during sintering. This is especially critical in die compaction where friction along vertical die walls and punch faces must be minimized through the use of admixed lubricants or die wall lubricants.

Corollary: Uniform powder loading is required to achieve a uniform dimensional change during sintering. Because the sintering rate is density dependent, a nonuniform distribution of powder will produce a nonuniform dimensional change during sintering. For injection molding, this means that the volume fraction of binder should be uniform throughout the green part. For multilevel die pressed compacts, this means that multiple pressing

motions should be used so that the proper powder distribution is achieved before consolidation starts. In die pressing there is negligible transfer of powder between cavity sections while pressure is applied.

Corollary: Prior to sintering but after debinding, injection molded parts must be supported because particle bonding at this point is simple cohesion. After ejection from the mold, an injection molded shape is held together by the binder. Prior to sintering, the binder is removed, leaving a time period when the only force holding the powder mass together is particle cohesion plus residual binder. A supporting bed of an unreactive matter such as alumina spheres may be necessary.

Guideline 2b: Ignore Guideline 2a if powder metallurgy is the only method that can be used to produce a particular material. In some cases powder metallurgy offers a way to process a unique material. In these cases, the uniqueness is the material often outweighs the economics of dimensional control so that substantial machining or secondary processing is acceptable.

Guideline 3: Metallurgical bonding of particles must be achieved during the consolidation process. After porosity, the next most important characteristic for achieving a usable part is metallurgical bonding or welding of the particles. Sintering is the most common process for accomplishing this bonding. The alternative to sintering is shear deformation of particles while under a general state of compression. In processes such as forging and extrusion, the particle deformation and local pressures are sufficiently high that strong welds develop between particles.

Corollary: Spherical particles should not be cold pressed if they are to serve a structural function. Cold pressing of spherical powders does not result in significant mechanical bonding of particles and green strength is poor. With careful handling, cold pressing of spherical powder can be accomplished, followed by sintering to achieve particle bonding; P/M filters are an example.

Corollary: The particle surface quality directly effects the strength of the particle bond. Sintering is not effective in improving mechanical properties if particle surface contaminants such as carbides or oxides block diffusion of alloy species. Therefore, sintering requires clean surfaces or it must include a surface cleaning step such as deoxidation.

Corollary: The mode of densification affects the quality of the interparticle bonding. The strength of the bond between powder particles is improved by shear deformation in comparison to repressing or isostatic compaction. Shear plus pressure breaks up surface contaminants and promotes particle bonding. As surface cleanliness is improved toward being contaminant free, there is less difference between consolidation processes involving high or low amounts of shear.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Introduction

MOST POWDERS receive at least one treatment prior to compaction. These treatments are tailored to the use of the powder and may include (a) particle size distribution adjustment through screening and/or air classifying, (b) annealing for the purpose of improving compacting properties, (c) lubricant addition for compacting grade powders, (d) mixing of different powders for premixes, and (e) blending of powders and powder mixes to homogenize their various components. These treatments are usually performed by the powder producer. The quality of these treatments can greatly affect the uniformity and consistency of sintered part properties. With increasing emphasis on zero defect manufacture, the treatments have received more attention in recent years.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Classifying/Screening

Many powder production processes yield relatively broad particle size distribution, and because of the many manufacturing variables, the distributions and average particle sizes may exhibit marked lot-to-lot variations, which contribute to the variation of important powder and sintered part properties. Classifying and screening are used to render the particle size distributions of powders more uniform with well-defined upper particle size limits. Powder producers often manufacture series of powders that differ only in particle size distribution. Such powders exhibit "graded" differences in dimensional change during sintering. For filter manufacture, classifying and screening are used to generate narrowly sized powder fractions for controlled pore size in filters and flow restrictors.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Mixtures and Segregation

Most P/M powders are multicomponent systems and, therefore, are subject to segregation. Segregation is even possible in a one-component metal powder if, for instance, coarse and fine powder particles "demix" as a result of vibration. The opportunity for powder segregation exists in processes such as shipping and the filling of hoppers and compaction dies, where individual components exhibit different flow rates due to differences in particle size, shape, density, surface roughness, and other properties.

The most widely used P/M compacting grade powders are mixtures of iron with graphite, copper, nickel, and/or molybdenum. The preferred use of powder mixtures rather than prealloyed powders is related to several factors. The most important one is that elemental powder mixtures generally possess significantly higher compressibilities than their prealloyed counterparts. Secondly, powder mixtures are usually less expensive than prealloyed powders. Finally, powder mixtures more often can be formulated to provide transient liquid phases during sintering, which can reduce sintering times and improve mechanical properties.

In most powder mixtures, the base powder typically comprises 90% or more of the powder mixture. Since the other components are present in only small amounts, and their alloying effects are powerful, it is very important that they are uniformly distributed; homogeneity of the powder must be preserved during shipping and handling at the parts producer's site until compaction is completed. Without such precautions, the properties of the sintered parts are not optimal and the standard deviation, that is, the scatter of the properties, can be quite large.

Powder Treatments and Lubrication

Stabilization of Powder Mixtures

Because of the wide use of powder mixtures and their sensitivity to demixing, much work has been done towards the stabilization of powder mixtures.

Stabilizers. A powder mixture is optimally mixed if its components approach a random (statistical) distribution free of agglomeration (Fig. 1). The quality of mixing can be measured by the number of particle contacts (in green compacts) between identical or different powder components as illustrated in Fig. 2 for iron-copper mixtures, or by the chemical analysis of appropriate samples taken from the powder mixture.

Fig. 1 Schematic representation of particle patterns in a powder mixture. (a) Ordered. (b) Agglomerated. (c) Statistical (random) distribution. (d) Demixed or segregated

Fig. 2 Effect of stabilizer on iron-iron contact formation in binary iron-copper system. Lower curve represents theoretical random mixture.

Blenders and mixers that rely mainly on gravity (tumblers) are suitable for powders that mix readily. More intense mixing is accomplished with low-shear agitated-type blenders that use ribbons, slow-speed paddles, screw-type augers, or other means of motion. Figure 3 illustrates how spherical powders mix quite readily, but also are subject to demixing or overblending. Consequently, mixing should be stopped once a near-random distribution has been achieved. The variability coefficient in Fig. 3 represents the standard deviation of the measured degree of mixing divided by the average value of the measured property. The quality of the mixture improves with decreasing variability coefficient.

Fig. 3 Effect of particle size and shape of components of 90%Fe-10%Cu mixtures on degree of blending. Quality of blending improves as variability coefficient decreases. Particle size and shape for components: (a) Cu, 200 to 300 μm ; Fe, <63 μm of spherical particle shape. (b) Cu 200 to 315 μm ; Fe, 100 to 200 μm of spherical particle shape. (c) Cu, 200 to 315 μm ; Fe, <63 μm of irregular particle shape. (d) Cu, 200 to 315 μm ; Fe, 100 to 200 μm of irregular particle shape

Demixing is often caused by the accumulation of electric charges, which frequently can be dissipated by the addition of a small amount of water. Surfactants and stabilizers are sometimes used to improve the flow of materials. They consist of wetting liquids and oils, which have no negative effects on the sintering process. Figure 4 shows the beneficial effect of oleic acid (dissolved in benzene) for 90%Fe-10%Al mixtures. In this example, the best mixture results from the addition of the optimized amount of a stabilizer after eight minutes of mixing, when the mixture has approached a random distribution (curved).

Fig. 4 Effect of stabilizer on degree of blending of 90%Fe-10%Al mixtures. Particle size for both components: 100 to 200 μm . Stabilizer: benzeneloleic acid. (a) Without stabilizer. (b) With 1.0% stabilizer. (c) 1.0% stabilizer added after 8 min of blending. (d) 3% stabilizer added after 8 min of blending

Diffusion-Bonded Powders. In a diffusion-bonded powder, a powder mixture is heated in a reducing atmosphere to yield a sintered powder cake, which after grinding, produces a powder that consists of agglomerates of the components of the powder. The process is controlled so that the degree of alloying among the different components is only small. This retains much of the desirable high-compressibility characteristics of the original elemental powder mixture and minimizes or eliminates the demixing tendency of such a powder. As a bonus, green strength is usually increased.

Binder-Treated Powder. In recent years powder producers have developed proprietary binders that are used in small amounts to bond fine graphite onto the coarser iron particles. Such powders reduce the dusting of a powder, and improve several important engineering properties of the sintered parts due to the more uniform concentration of carbon in the final parts.

Prealloyed Powders. Despite the widespread use of powder mixtures, the use of prealloyed powders in the structural parts industry has been increasing. In the low-alloy steel segment, nickel, molybdenum, and manganese are used as alloying elements to provide greater hardenability than is possible with admixed copper or nickel. Admixed nickel requires economically prohibitive sintering times (even at high sintering temperatures) for complete alloying. Higher alloyed powders, such as stainless steels, tool steels, and superalloys, are all prealloyed powders. The requirement of complete alloying in these alloy classes makes the elemental powder approach impractical. The problem of low compressibility, that is, low green density and/or low green strength, is solved by high-temperature and liquid phase sintering, and through the use of special consolidation methods, such as hot isostatic pressing and extrusion.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Annealing

Although the term annealing refers to a heat treatment that renders a metal soft by the removal of strain, in P/M, the term is used more broadly and includes the softening of a powder by the removal of interstitials, particularly carbon, nitrogen, and oxygen. Powders that have been work hardened through milling; powders that contain residual amounts of carbon, oxygen, or nitrogen; and powders that contain objectionable surface oxide films are most often subjected to this type of annealing. Examples include sponge and atomized iron powders, carbonyl and electrolytic iron powders, tool steel powders, and ferritic stainless steel powders. In most cases, annealing is performed in a reducing atmosphere, which not only protects the powder against oxidation, but also removes surface and interior oxides. Annealing improves the compressibility and green strength of a powder due to the softening of the metal. Frequently, annealing also produces slightly agglomerated powders with lower apparent densities and further increases in green strength.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Lubrication

Lubrication is essential to reduce friction between the pressed compact and the rigid tool components when compacting metal powders in steel or carbide tooling. Extremely high part ejection pressures and, ultimately, seizing and excessive tool wear result without proper lubrication. In addition, the surface quality of the part is detrimentally affected. Although much work has been done with systems where the tooling itself is lubricated, these systems generally have not proved effective high-volume P/M parts production. Parts produced by isostatic compaction do not require lubrication, due to the absence of high frictional forces during this type of processing.

Compacting grade metal powders are lubricated to facilitate part ejection from the die and to minimize die wear. Lubricants can strongly affect compacting and sintering properties of a powder. For this reason, powder producers try to optimize amount, composition, and structure of a lubricant to not only reduce friction during powder compaction, but also to protect the powder against oxidation and to obtain consistent apparent density and powder flowability, proper dimensional change during sintering, and maximum and consistent mechanical properties of the sintered parts.

Although a lubricant largely evaporates and/or decomposes in the preheating zone of a sintering furnace, its interactions and reactions with the metal powder can have critical consequences. Potential problems range from lubricant segregation, burnout, and blistering to carbonization and lubricant residue interference. Lubricant performance also depends on part density, metal powder composition, and particle size.

Lubricant Selection

In the majority of P/M applications, the lubricant is premixed directly with the metal powder. Stearic acid, zinc stearate, lithium stearate, and synthetic waxes, such as Acrawax, are the most popular lubricants. Lubricant selection is based primarily on the ability of the lubricant to adhere to metal particle surfaces. The amount of lubricant added depends on many factors, including composition of the metal powder, type of tooling, compacted density, and complexity of the part. Amounts generally vary from 0.5 to 1.5 wt%.

Lithium stearate is widely used in stainless steel powders because of its beneficial effect on compressibility. Lithium stearate and zinc stearate mixtures are used in brass and nickel silver powders to produce stainfree parts. Synthetic waxes with their low moisture and ash contents are widely used for high-density parts where ash residues are objectionable. Multicomponent lubricants permit the powder producer to adjust or influence the packing, pressing, and sintering characteristics of powder. The use of die wall rather than admixed powder lubrication is still in the development stage.

Ferrous Materials

Although lubricants are a necessary addition to compacting metal powders, they can have some critical, and often deleterious, effects on the ultimate premix. Hoeganaes Corporation (Ref 1) has made a comprehensive study of lubricants and their influence on the properties of iron premixes. Lubricant properties, such as bulk density and particle size, are very important; for example, high-bulk density and large particle size provide good flow and low stripping pressure, as illustrated in Fig. 5 and 6. To minimize premix segregation, the particle size of the lubricant must be smaller than the size of the largest particle of iron powder; for example, a 150- to 200-mesh (104- to 75- μm) lubricant should be used with 100-mesh (150- μm) iron powder.

Fig. 6 Relationship of stripping pressure and bulk density of iron powders with 1.0% zinc stearate lubricant. Source: Ref 1

The melting point of the lubricant must be high enough to prevent melting or softening from heat developed during mixing. If this occurs, flow deteriorates, apparent density decreases, and the mix tends to agglomerate.

Higher lubricant content yields poorer flow, lower apparent density, and lower stripping pressure. Figure 7(a) shows the effect of lubricant content on apparent density of atomized stainless steel powder. The effect of increasing amounts of three lubricants on the flow of iron powder is shown in Fig. 7(b) and 8.

Mixing time of 30 min. Source: Ref 1

Stripping pressure is the initial amount of pressure required to start the ejection process of a green compact from the die after compaction. The sliding pressure is lower than the stripping pressure and can be defined as the pressure required to complete the compact ejection cycle. Both stripping and sliding pressures are dependent on the compaction pressure and type of lubricant, as shown in Fig. 9 and 10. Thus, different lubricants may be required for steel and carbide tooling materials.

Fig. 9 Effect of compaction pressure and 0.75% lubricant on stripping pressure of Ancorsteel 45P (Ancorsteel

1000B + 2.90 wt% ferro-phosphorus)

Fig. 10 Effect of compaction pressure and 0.75 wt% lubricant on the sliding pressure of Anchorsteel 45P (Anchorsteel 1000B + 2.90 wt% ferro-phosphorus)

Stripping strength can vary considerably with the type of lubricant used. When compared to parts pressed without lubricant, zinc stearate and stearic acid decrease sintered strength only slightly, as illustrated by Fig. 11 and 12. However, several lubricants, such as calcium and barium stearates, added to pure iron or to an iron and 1% graphite mixture cause significantly large decreases in sintered strength, as shown in Fig. 13. The appearance of P/M parts after sintering also can be affected by lubricants. Although the effect on iron parts is not as significant as with brass and nickel-silver powders, spotty surfaces and discoloration can be a major concern. Lubricants that vaporize completely during sintering generally leave a clean surface. Dark mottled surfaces occasionally result from zinc and calcium stearate lubricants, due to condensed zinc metal or calcium oxide deposits.

Lubricant removal, prior to the actual sinter operation, is vitally important for several reasons. Generally, this removal is accomplished during the sintering preheat operation and is referred to as "burn-off." Because of highly adverse effects of residual lubricant carbon deposits when sintering stainless steel, resulting in lowered corrosion resistance, Moyer (Ref 2) conducted an extensive study of the burn-off characteristics of common lubricants (lithium stearate, zinc stearate, Acrawax C, and Nopco Wax) in 316L powder compacts. Burn-off temperatures of 370, 425, and 480 °C (700, 800, and 900 °F) were used in both air and dissociated ammonia atmospheres. This study revealed that the waxes leave no residue at 425 °C (800 °F) or higher; the stearates, however, leave approximately 15% residue even when burned at temperatures up to 540 °C (1000 °F). Maximum lubricant burn-off is achieved at about 425 °C (800 °F). Burn-off is less controllable in

dissociated ammonia, and the amount of lubricant removed decreases as the compacting pressure is increased. Carbon burn-off is incomplete when compacts are burned off in a dissociated ammonia atmosphere.

Nonferrous Materials

Many lubricants frequently used in iron-base powder systems have not been effective in all copper-base prealloyed systems. Without lubricant system development, primarily lithium stearate, it is unlikely that brass and nickel-silver P/M parts would hold the strong market position that they do today (Ref 3). The use of lithium stearate overcame many early sintering problems and provided consistently high properties in brass P/M parts.

Lubricants such as zinc stearate, lithium stearate, stearic acid, and Acrawax have been used successfully with conventional premixed bronze materials (90%Cu-10%Sn). A recent study (Ref 4) comparing the two stearates and Acrawax revealed slightly better compressibility and lower ejection pressures with zinc stearate. Furthermore, green strength increased with decreased amounts of lubricant, and Acrawax provided superior green strength zinc and lithium stearate.

Bi-lubricant systems, such as lithium-zinc stearate, provide the advantages of high physical properties and relatively clean surface appearance. Lithium stearate and lithium-zinc stearate lubricant additions in the range of 0.5 to 0.75% are used most often in brass and nickel-silver parts. Although waxes are excellent for maintaining green strength, their use results in lower apparent densities, higher briquetting pressures, and lower sintered strengths in brass parts.

Frequently, a bi-lubricant system of zinc stearate and stearic acid at 0.75 wt% is employed for conventional bronze premix blends; these two lubricants complement each other. Stearic acid has excellent lubricating characteristics, but its spherical morphology tends to promote segregation, therefore, the irregular shape of the zinc stearate particles provides a supportive interlocking effect. Acrawax often is used alone to increase green strength, although it can lower the apparent density and retard the flow of bronze premixes.

Lubricants play a unique role in the production of copper P/M parts for high electrical conductivity applications (Ref 5). Lithium stearate allows the highest electrical conductivity among lubricated compacts, as illustrated in Fig. 14. Compacts pressed at 275 MPa (20 tsi), using a synthetic wax lubricant, have conductivities of about 74% IACS; similar compacts produced with lithium stearate exhibit conductivities of about 86%. The effect of the quantity of lubricant on electrical conductivity of copper P/M parts is shown in Fig. 15. The electrical conductivity reaches a maximum with approximately 0.6% lithium stearate in compacts pressed at 275 MPa (20 tsi) and with approximately 0.5% at 415 MPa (30 tsi).

Fig. 14 Effect of lubricant on electrical conductivity of copper P/M parts. Compacting pressure: (a) 276 MPa (20 tsi); (b) 414 MPa (30 tsi)

Fig. 15 Effect of lubricant quantity on the electrical conductivity of copper P/M parts

Synthetic organic waxes, which have low moisture and ash content, are employed in the production of aluminum P/M premixes (Ref 6). The addition of 1.5% lubricant (nominally) permits the consistent production of high-density aluminum

P/M parts with fine surface quality and eliminates tool problems with seizing and cold welding. High sintered properties are achieved because these lubricants leave virtually no ash to interfere with particle bonding during sintering.

Mechanical Behavior of Metal Powders and Powder Compaction Modeling

J.R.L. Trasorras and R. Parameswaran, Federal-Mogul, Dayton, Ohio; A.C.F. Cocks, Leicester University, Leicester, England

Introduction

CONSOLIDATION OF METAL POWDER into useful products generally follows a three-step process: (1) powder transfer into a container or die, (2) powder compaction through applied force, and (3) sintering. Particular processes combine two of these steps into one. For example, hot isostatic pressing combines steps two and three through the simultaneous application of pressure and temperature in an autoclave. This article describes step two, the mechanical response of the powder to the applied compaction forces. Density of the powder transferred into the container depends on the properties of the powder and on the method of transfer, which may include tapping and vibrating. Consideration of packing density is beyond the scope of this article; however, a comprehensive review of this topic can be found in Ref 1. Proper design of compaction processes requires a description of the mechanical or thermomechanical behavior of the powder. Issues related to applications of practical interest include:

- *Compaction in rigid dies:* Density distribution in the compact, effect of tooling motion histories on density, tooling stresses and tooling deflections, stresses in the compact during ejection and fracture likelihood
- *Cold isostatic pressing:* Geometric distortion of the pressed component, effect of container dimensions and material on distortion
- *Hot isostatic pressing:* Geometric distortion of the pressed component, effect of pressure and temperature cycles on distortion, effect of container design on distortion
- *Powder forging:* Density distribution in the formed part, forging loads, and tooling stresses

Unfortunately, the complex nature of powder mechanical behavior, coupled with complex geometry and boundary conditions, precludes analytical solutions to these problems. During the late 1980s, the maturing of numerical solutions to finite strain plasticity allowed initial attempts at modeling powder compaction processes. Powder compaction modeling has not achieved widespread industrial use yet. However, many useful and encouraging results have been published, and it seems likely that during the next decade, modeling will become central to the design of compaction processes.

Formally, powder compaction modeling requires the solution of a boundary value problem--a set of partial differential equations representing:

- *Balance laws:* conservation of mass, momentum balance, and conservation of energy
- *Constitutive laws:* stress-strain relation and friction laws

The finite element method (FEM) is the numerical technique most widely used to solve these equations. Modern FEM codes incorporate constitutive models for a wide variety of materials. Some of them are suited to modeling metal powders. Furthermore, these codes also provide facilities for the user to implement a particular constitutive law.

Constitutive Models for Metal Powder Compaction

This section examines the response of powder compacts under mechanical loading histories that are typical of those experienced during the manufacture of powder metal parts. Deformation of a powder compact occurs as the result of rearrangement and plastic deformation of the particles. Frictional resistance, as particles slide over each other, can also contribute to the macroscopic response. If the packing is initially loose, then the initial stages of compaction are dominated by particle rearrangement, with little or no plastic deformation occurring between the contacting particles. If, however, the initial apparent density of the powder is relatively high, further macroscopic plastic deformation under constrained compressive stress states is dominated by plastic deformation of the particles themselves.

Knowledge of the major physical processes that occur when a powder compact is deformed can be used to guide the development of constitutive models of the compaction process. At the microlevel, the constitutive response of fully dense materials governs plastic deformation between the contacting particles. The macroscopic response can then be determined by combining the contributions from individual contacts. There are general theoretical techniques that can be employed to achieve this and determine what general statements can be made about the structure of the macroscopic constitutive laws. Micromechanical models have been developed using these techniques. It may not be appropriate to precisely follow this route, but, instead, to develop empirical constitutive laws based on observations made at the macroscopic level. The results then provide a suitable structure and general guidelines for the construction of these models. As the material approaches full density, these models should reduce to classical incompressible models. Therefore, these models serve a second purpose; they provide a starting point from which more general constitutive relationships can be developed.

Throughout the article, the response of an element of material in a particle of the compact (referred to as a "microscopic element") is identified in terms of the local stress σ_{ij} and local strain ϵ_{ij} . When evaluating the response of a powder compact, a representative "macroscopic element" of material, which contains a large number of particles but is small compared to the size of a pressed component, is identified. The response of such an element is expressed in terms of a macroscopic average stress Σ_{ij} and strain E_{ij} .

Deformation of Powder Compacts: Experimental Observations

Before examining the structure of constitutive laws for powder compaction, it is instructive to identify the major physical processes that occur within the compact as it is deformed and to determine how these are likely to influence the macroscopic behavior. When the powder is initially poured into a die or mold, the particles are arranged randomly with particles only in point contact with each other.

Consider the situation where the compact is densified hydrostatically. As the pressure is increased, plastic flow occurs in the vicinity of the contacts. As a result, the contact zones spread, the centers of the particles move closer together, and the material densifies. During the initial stages of this process, the porosity remains connected, consisting of a network of interconnected channels threading through the material. In the micromechanical models, this is referred to as stage 1 compaction. As the material is densified further, the channels pinch off, leaving a distribution of isolated pores (stage 2). Throughout this process, because of the initial random structure, the porosity is randomly distributed throughout the material, particularly during stage 1 compaction. If, however, the sample is much larger than the mean particle size, no preferential orientations or distributions of pores develop, and the structure remains macroscopically isotropic. A single

state variable can then be used to describe the structure and macroscopic response. A convenient state variable is the relative density D , which is defined as the ratio of the density of the compact to the density of the material, so that at full density $D = 1$.

In practical compaction processes, the densifying material can see complex stress states and histories. As a result, the structure that develops is no longer isotropic, and it may not be appropriate to describe this structure and the macroscopic response using a single state variable. For example, consider the case of frictionless closed-die compaction. As a cylinder is compacted along its axis, there is no straining in the transverse direction. The contact patches that develop between the deforming particles are therefore larger normal to the direction of loading than along the axis. Also, the size of these patches is different from those in a compact that has been densified hydrostatically to the same relative density. Thus, the relative density does not uniquely describe either the microstructure or the macroscopic response.

Any constitutive law that is developed needs to be validated experimentally. An examination of the types of experiments that have been performed and how the results from these tests are commonly presented follows. The analysis is based on the identification of a yield surface for the material (which is a surface in stress space within which the material responds elastically; plastic deformation can only occur for stress states on the yield surface). The size and shape of the yield surface is a function of the history of loading. The yield surface can be determined using a number of different methods. A number of samples can be prepared in the same way (for example, hydrostatically compacted to the same relative density). Each sample is then loaded along a different path in stress space until it yields. The yield surface is then formed by connecting the different yield points. Alternatively, a single specimen can be used. After compacting to the desired state, a series of probing experiments can be performed by unloading and reloading along a range of different stress paths until yield occurs. The yield surface can be mapped out in exactly the same way as before. When using this method, it is important to ensure that only a small amount of plastic straining occurs during each probe so that there is no significant change of microstructure (i.e., state) over the series of probing tests.

When examining a range of different stress states, it proves convenient to present the results in terms of global measures of stress. Two convenient quantities are the von Mises effective stress, Σ_e , and the mean (or hydrostatic) stress, Σ_m . If Σ_1 , Σ_2 , and Σ_3 are the principal stresses,

$$\Sigma_e = \sqrt{\frac{1}{2} [(\Sigma_1 - \Sigma_2)^2 + (\Sigma_2 - \Sigma_3)^2 + (\Sigma_3 - \Sigma_1)^2]} \quad (\text{Eq 1})$$

and

$$\Sigma_m = \frac{1}{3} (\Sigma_1 + \Sigma_2 + \Sigma_3) \quad (\text{Eq 2})$$

More general definitions of these stresses are provided in the following section.

Alternatively, instead of using Σ_m , the material response can be presented in terms of the hydrostatic component of stress (or pressure) $P = -\Sigma_m$. These definitions are used interchangeably throughout the article.

Many of the experimental methods used today to evaluate the behavior of metal powders have been inspired by techniques used to test soils. Most published data has been generated using such procedures. Before examining the material data in detail, it proves instructive to first examine the general features of the most common testing methods.

It is convenient to represent the yield function, as well as the stress paths during testing, in the $P - \Sigma_e$ plane. In this representation, the closer a point is to the ordinate (Σ_e axis), the more shear experienced in the material; the closer it is to the abscissa (P axis), the more hydrostatic pressure experienced. The typical powder compaction process involves stress states that have a high-pressure component, a natural consequence of the confinement of the powder in a die cavity.

Figure 1 shows a schematic representation of the load paths corresponding to the different test procedures:

- *Simple shear test:* This is marked by a complete absence of any hydrostatic load. This test has little value in the context of loose powders and can only be applied to sintered powders or porous materials.

- *Simple compression test:* This is once again a shear-dominated test, with friction at the interface of the powder and dies assumed absent. As with the previous case, this test can realistically only be used for sintered powders or porous materials.
- *Triaxial test:* The primary advantage of this test is that a variety of stress paths can be examined through a combination of compressive stresses in axial Σ_z and radial Σ_r directions. A detailed description of this test is provided in the section "Experimental Determination of Powder Material Constitutive Properties and Functions" in this article. The effective and hydrostatic components of stress for this loading situation are given by $\Sigma_e = |\Sigma_z - \Sigma_r|$ and $P = \frac{1}{3}(2\Sigma_y + \Sigma_z)$.
- *Closed die compaction:* The state of stress in the powder in this test is possibly the best description of the actual stress state in a typical compaction. This test does not lend itself to parameter extraction procedures because friction is present at the die walls. It is possible, however, to simulate frictionless closed die compaction in a triaxial cell.
- *Hydrostatic compaction:* The state of stress during this test is one of pressure alone with shear components completely absent. This test is easy to set up and provides the compressibility of the material.

Fig. 1 Schematic representation of the load paths corresponding to the different test procedures. Source: Ref 31

All the cases illustrated in Fig. 1 involve the testing of cylindrical specimens. The inherent symmetry in the shape and loading can be exploited to simplify the analytical treatment required for the extraction of material parameters.

It should be noted that results from a particular testing procedure might be used to extract material parameters for different constitutive models. Simplifying assumptions are an essential ingredient in such determinations. For instance, friction is inevitably present in most testing procedures. However, it often becomes necessary to ignore the effects of friction in the extraction procedure, because not doing so may seriously impair the ability to obtain reasonable values for material parameters.

Kim et al. (Ref 5) cold isostatically pressed tubes of iron powder (Hoeganaes ASC 100-29) to relative densities in the range $D = 0.8$ to 0.85 . These tubes were then sintered at 1150°C for 1 h in a hydrogen atmosphere. The tubes were then tested in combined tension, Σ , and torsion, T . Typical yield surfaces obtained from these experiments are shown in Fig. 2, where the results are normalized with respect to the yield strength of the fully dense material, σ_y . The sintering process has bonded the particles, imparting significant tensile strength to the compact. A number of studies for determining the mechanical properties of powder compacts employ the same type of procedure. For example, the experimental studies of Kuhn and Downey (Ref 6) and Shima and Oyane (Ref 7), which form the basis for a widely used constitutive law for powder compaction, were performed on sintered compacts. Brown and Weber (Ref 8) demonstrated that the mechanical response of compacted and then sintered powders is very different from that of identical powders that have only been compacted. Watson and Wert (Ref 9) compacted aluminum powders hydrostatically and by using closed-die compaction. They performed uniaxial tensile and compressive tests on these samples to construct the yield surface.

Fig. 2 Yield surfaces determined by Kim et al. (Ref 5) from tension/torsion tests on sintered iron powders

Akisanya et al. (Ref 10) used the probing method to determine yield surfaces for samples of spherical powders, which were either hydrostatically compacted or compacted by simulating closed-die compaction. These tests were performed using a triaxial cell in which hydrostatic pressure and uniaxial compression could be applied independently. Yield surfaces obtained for a relative density of 0.8 are shown in Fig. 3 using the axes of $\Sigma_s = \Sigma_z - \Sigma_r$ and Σ_m . Note that in these experiments $\Sigma_r > \Sigma_z$ and thus Σ_s is negative with $\Sigma_s = -\Sigma_e$. It is important to note that the shape of the yield surfaces obtained by compacting the samples using these two different methods are significantly different from each other. Thus, the states of the materials are different even though the densities are the same.

Fig. 3 Yield surface for spherical copper powders determined by Akisanya et al. (Ref 10) for isostatically pressed and close-die compacted samples

Another convenient way of presenting experimental data is in the form of isodensity plots. These plots are constructed by loading samples proportionally (either by maintaining the stresses or the strains proportional to each other) and then determining the stress states that correspond to a given density. If the material response can be described using the relative density as the only state variable, then these surfaces would be equivalent to the yield surfaces of the material. It is evident from the results of Fig. 3 that more than one state variable is required to describe the response. However, in many practical situations, an element of material experiences near proportional loading and isodensity or similar plots provide valuable information about the constitutive behavior. Brown and Abou-Chedid (Ref 11) constructed a series of isodensity plots in $\Sigma_e - \Sigma_m$ space for spherical copper and sponge iron (Hoeganaes MH-100) powders (Fig. 4, 5). The solid symbols in these figures represent the yield strength in uniaxial compression following biaxial compression to the desired density. The major observations here are the different forms of the surface for the different powders, and the fact that the spherical powder has limited strength in uniaxial compression. These conclusions are consistent with the experiments of Akisanya et al. (Ref 10) presented in Fig. 3. The irregular powders, however, exhibit significant strength in uniaxial compression. Also, the irregular powders tested by Watson and Wert (Ref 9) had a significant yield strength when loaded in tension, while samples of spherical powder compacts can readily be broken in tension, often by hand, due to the lack of interlocking of the particles. These plots will be discussed and evaluated in the following sections. There are however, three important points to note at this stage:

- It is possible to identify a yield surface for a powder compact.
- The state of the material is a function of the prior history of loading. This influences the size and shape of the yield surface.
- The yield behavior depends on the morphology of the powder particles. Irregular particles interlock, giving tensile strength, while compacts of smooth spherical particles can be readily pulled apart.

Fig. 4 Isodensity surfaces for spherical copper powders tested by Brown and Abou-Chedid (Ref 11)

Fig. 5 Isodensity surfaces for irregular iron powders tested by Brown and Abou-Chedid (Ref 11)

Elastoplastic Constitutive Behavior

The constitutive behavior is discussed within the framework of small deformation theory of plasticity, which allows the decomposition of the total strain into elastic and plastic components and development of relatively simple expressions for the constitutive response. In practice, large plastic straining of a body can occur during the compaction process. The general forms of expression are still applicable, provided appropriate measures of stress, strain, stress-rate, and deformation-rate for these problems are defined. At this stage, it is not necessary to precisely determine what these definitions are. All necessary information can be determined by making the simple assumption of small strains. Start by considering the response of a microscopic continuum element of material (i.e., the response of the individual particles that form the compact).

Assume that the total strain, ϵ_{ij} , a body experiences can be decomposed into elastic and plastic components, such that:

$$\epsilon_{ij} = \epsilon_{ij}^e + \epsilon_{ij}^p \quad (\text{Eq 3})$$

Where appropriate, the index notation for tensorial quantities is used to represent the constitutive response. The indices i and j can have a value in the range of 1 to 3. A repeating suffix implies summation over this range (thus, $\epsilon_{ij} = \epsilon_{11} + \epsilon_{22} + \epsilon_{33}$).

Elastic Behavior. The elastic strains depend on the current stress. For a linear elastic material,

$$\epsilon_{ij}^e = C_{ijkl} \sigma_{kl} \quad (\text{Eq 4})$$

where C_{ijkl} is the elastic compliance matrix. If the material response is isotropic, it is more convenient to decompose the strain into deviatoric, ϵ_{ij}^{ed} , and volumetric, ϵ_v^e , components, such that:

$$\epsilon_{ij}^e = \epsilon_{ij}^{ed} + \frac{1}{3} \epsilon_v^e \delta_{ij} = \frac{s_{ij}}{2G} + \frac{\sigma_m}{3K} \delta_{ij} \quad (\text{Eq 5})$$

where G is the shear modulus, K is the bulk modulus, $s_{ij} = \sigma_{ij} - \frac{1}{3} \sigma_{kk} \delta_{ij} = \sigma_{ij} - \sigma_m \delta_{ij}$ are the deviatoric components of stress, $\sigma_m = \frac{1}{3} \sigma_{kk}$ is the mean stress, and δ_{ij} is the Kronecker delta function ($\delta_{ij} = 0$ for $i \neq j$; $\delta_{ij} = 1$ for $i = j$). For a fully dense material, G and K are material constants. If the material is porous, both these moduli can be a function of the relative density of the material. This point is revisited later in the article in an examination of the constitutive response of powder compacts.

Classical Plasticity for Incompressible Materials. Central to the development of constitutive laws for plastically deforming materials is the concept of a yield surface. Here a more precise definition of ways in which the changing state of the material can be modeled is presented. The discussion is limited to classical plasticity concepts for fully dense materials, where plastic flow occurs at constant volume. Porous bodies are presented in subsequent sections.

A yield surface is shown schematically in Fig. 6 in principal plane stress space, in which there are two measures of stress σ_1 and σ_2 . Mathematically, this surface can be defined by the equation:

$$f(\sigma_{ij}) = 0 \quad (\text{Eq 6})$$

where $f(\sigma_{ij})$ is a function of stress. For example, for an isotropic incompressible material, a suitable form of this expression is:

$$f(\sigma_{ij}) = \sigma_e - \sigma_y \quad (\text{Eq 7})$$

where σ_y is the yield strength of the material in uniaxial tension and σ_e is the von Mises effective stress, given by:

$$\sigma_e = \sqrt{\frac{3}{2} s_{ij} s_{ij}} \quad (\text{Eq 8})$$

In principal plane-stress space,

$$\sigma_e = \sqrt{\sigma_1^2 + \sigma_2^2 - \sigma_1 \sigma_2} \quad (\text{Eq 9})$$

Fig. 6 Schematic of yield surface in plane-stress space, showing strain increment vector normal to the yield surface

Equation 9 then represents the von Mises ellipse shown in Fig. 6. If $f < 0$, the material response is elastic, and if $f = 0$ (i.e., if the stress state is on the yield surface), the material is able to deform plastically. The increments of plastic strain at yield are related through the associated flow rule:

$$d\epsilon_{ij}^p = \lambda \frac{\partial f}{\partial \sigma_{ij}} \quad (\text{Eq 10})$$

where λ is a plastic multiplier. This equation simply states that the strain increment vector is normal to the yield surface in stress space. Additional information is needed to determine the exact value of λ .

For the yield condition of Eq 7,

$$\frac{\partial f}{\partial \sigma_{ij}} = \frac{\partial \sigma_e}{\partial \sigma_{ij}} = \frac{\partial \sigma_e}{\partial s_{ij}} = \frac{3}{2} \frac{s_{ij}}{\sigma_e} \quad (\text{Eq 11})$$

Now,

$$d\epsilon_{ij}^p = \lambda \frac{3}{2} \frac{s_{ij}}{\sigma_e} \quad (\text{Eq 12})$$

Also,

$$d\epsilon_{ij}^p d\epsilon_{ij}^p = \lambda^2 \frac{9}{4} \frac{s_{ij}s_{ij}}{\sigma_e^2} = \frac{3}{2} \lambda^2 \quad (\text{Eq 13})$$

Thus,

$$\lambda = \sqrt{\frac{2}{3} d\epsilon_{ij}^p d\epsilon_{ij}^p} = d\epsilon_e^p \quad (\text{Eq 14})$$

where $d\epsilon_e^p$ is an effective strain increment. The volumetric component of the strain increment at yield is:

$$d\epsilon_v^p = d\epsilon_{ii}^p = \frac{3}{2} \frac{s_{ii}}{\sigma_e} = 0 \quad (\text{Eq 15})$$

which is consistent with the initial assumption of incompressibility.

This manipulation of equations is standard, but there are some important points to note:

- The effective stress, which drives the deformation, is only a function of the deviatoric stresses (i.e., it is independent of the magnitude of the mean stress).
- The strain increments at yield are proportional to the deviatoric components of stress.
- The deviatoric component of stress, and therefore the effective stress, drives changes of shape of an element.
- Volume changes are driven by the mean stress.

In the above description the magnitude of the strain increment at yield has not been determined; only the relative magnitudes of the strain components have been determined. To determine the magnitude, the evolution of the state of the material with time must be understood. In Eq 7, the state is represented in terms of the yield strength of the material. Use of a single state variable of this type implies isotropic behavior. Below, two particular forms of isotropic models are examined.

Perfect Plasticity. The simplest assumption is that the yield strength remains constant, in other words, the yield surface retains the same size and shape in stress space. The plastic strain increment $d\epsilon_{ij}^p$ can then have any value. In a structural problem, the exact value of the strain increment is determined either from the full elastoplastic response of the body or from any resulting geometry changes.

Isotropic Hardening. As the material is deformed plastically, the yield stress can increase. Consider the situation where yield strength is a function of the accumulated plastic strain ϵ_e^p :

$$\epsilon_e^p = \int_0^{\epsilon_e^p} d\epsilon_e^p \quad (\text{Eq 16})$$

that is,

$$\sigma_y = \sigma_y(\epsilon_e^p) \quad (\text{Eq 17})$$

and

$$d\sigma_y = \frac{d\sigma_y}{d\epsilon_e^p} d\epsilon_e^p = h(\sigma_y) d\epsilon_e^p \quad (\text{Eq 18})$$

where $h(\sigma_y)$ is the slope of a plot of yield strength against plastic strain in a standard uniaxial material test.

Plastic flow can only occur if the stress state is on the yield surface, in other words, plastic flow only occurs as the stress is increased from σ_{ij} to $\sigma_{ij} + d\sigma_{ij}$ if $f = 0$ throughout the increment and $(d\sigma_{ij})(\partial f / \partial \sigma_{ij}) > 0$. Then, differentiating (Eq 7) gives:

$$df = \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} + \frac{\partial f}{\partial \sigma_y} d\sigma_y = \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} - d\sigma_y = 0 \quad (\text{Eq 19})$$

Combining Eq 18 and 19 gives

$$d\epsilon_c^p = \frac{1}{h(\sigma_y)} \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} \quad (\text{Eq 20})$$

The individual strain increments can be obtained by combining Eq 20 with Eq 12 and 14.

In the above model, it is assumed that the material remains isotropic as it deforms plastically, so that the yield surface maintains the same shape and simply changes in size as plastic strain is accumulated. In practice, the material response can become anisotropic. One means of representing anisotropy is through the use of a kinematic hardening model, wherein the center of the yield surface in stress space is allowed to translate according to some rule. See Ref 12 for further information. As a different approach towards anisotropy, Hill (Ref 13) presents a generalized theory of plasticity that allows for a change in the shape of the yield surface, while the basic requirements of convexity and incompressibility are maintained.

There are many other types of constitutive laws that have been developed to model the response of plastically deforming materials. As in the models described here, these alternatives mainly consist of identifying a yield surface and developing appropriate laws for the expansion, translation, and change in shape of the surface as the material deforms plastically. These laws can contain many state variables, together with complex evolution laws. The choice of constitutive law depends on the type of loading histories being evaluated. If the stress history experienced by the material point is simple, then relatively simple constitutive laws adequately describe the material response. For example, for monotonic proportional loading, the kinematic and isotropic hardening models predict the same response provided they are fit to the same base data. A detailed knowledge of the shape and orientation of the entire yield surface and how these evolve with time is only required if complex loading histories are being considered. It should also be remembered that the more complex the constitutive law, the wider the range of tests that need to be devised to determine all the material parameters and the evolution equations for each of the state variables. When selecting the structure of a constitutive law, it is therefore important to first determine the type of stress history that each material point is likely to experience and to select the equations capable of capturing the major feature of the response.

In the following section, assume that the individual particles of a compact deform according to the constitutive models described in this section. This understanding provides a structure for the development of the constitutive laws for the compact.

The Structure of Constitutive Laws for Powder Material

Consider an element of a powder compact (Fig. 7), subjected to a macroscopic stress state Σ_{ij} , and experiencing strains E_{ij} . The strain can be decomposed into macroscopic elastic and plastic components, as before:

$$E_{ij} = E_{ij}^e + E_{ij}^p \quad (\text{Eq 21})$$

Assume that the elastic response is isotropic. The elastic constitutive law can then be expressed in the form of Eq 5:

$$E_{ij}^e = E_{ij}^{ed} + \frac{1}{3} E_v^e \delta_{ij} = \frac{S_{ij}}{2G} + \frac{\Sigma_m}{3K} \delta_{ij} \quad (\text{Eq 22})$$

where G and K are functions of the state of the material. Several techniques for determining the elastic moduli G and K are summarized in Table 1. It is sometimes more practical to measure Young's modulus E instead of shear modulus G . Shear modulus can be determined using $G = 3KE/9(K - E)$.

Table 1 Experimental techniques for the determination of elastic properties of powder compacts

Experimental technique	Elastic property	Comments	Reference
Triaxial test unloading	$E(D)$	Can determine E at low density (D is ~ 0.65 for atomized steel powders). Experimental apparatus is involved.	Ref 14
Resonant frequency	$E(D)$	Very accurate and repeatable. Simple experimental setup. Simple sample preparation. Commercial laboratories available that use this technique. Minimum density D is ~ 0.75 for atomized steel powders.	Ref 15
Ultrasound	$E(D)$	Higher scatter than resonant frequency. Able to determine anisotropic properties in a transverse rupture bar.	Ref 15
Hydrostatic test unloading	$K(D)$	Can determine K at low density (D is ~ 0.65 for atomized steel powders). Experimentally difficult at very high density.	Ref 14

Fig. 7 Macroscopic element of powder compact subjected to stresses Σ_{ij}

The variables E and K can be measured during the unloading of a triaxial compaction test and a hydrostatic compaction test, respectively. Another technique used to determine E is resonant frequency. The powder is compacted into a beam, typically a transverse rupture bar. The beam is excited through an impact load, and the natural vibration frequency is measured. This frequency can be used to compute E . Ultrasound has also been applied to the determination of E in compacted specimens.

Watson and Wert (Ref 9) measured the variation of G and K as a function of D for samples which had been compacted in closed die. They found that:

$$G = G_m \exp(8.15(D - 1)) \quad (\text{Eq 23})$$

$$\chi = \chi_m \exp(5(D - 1)) \quad (\text{Eq 24})$$

with

$$K = \chi + \frac{2}{3}G \quad (\text{Eq 25})$$

and G_m and χ_m representing the shear modulus and Lamé constant for the fully dense material, respectively.

If a microscopic element deforms plastically according to any of the models described, and there are no other dissipative mechanisms operating, then it is possible to identify a yield surface in stress space:

$$F = F(\Sigma_{ij}, S_\alpha) = 0 \quad (\text{Eq 26})$$

which is a function of stress and the state of the material, described in terms of a number of state variables, S_α . Plastic flow can only occur if the stress state is on the yield surface. It can further be shown that associated flow at the micro-level guarantees associated flow at the macroscopic level, thus:

$$dE_{ij}^p = \Lambda \frac{\partial F}{\partial \Sigma_{ij}} \quad (\text{Eq 27})$$

where Λ is the macroscopic plastic multiplier.

If frictional sliding contributed to the internal dissipative processes, then it is still possible to identify a yield surface, but associated plastic flow cannot be guaranteed. Fleck (Ref 16) has examined the two extremes of frictional behavior: free sliding; and sticking, whereby sliding can only occur by shear yielding in the vicinity of a contact. In each case, there is no frictional dissipation and associated flow can be guaranteed. The yield surface for intermediate frictional conditions should lie between the yield surfaces for these two situations. Fleck (Ref 16) found that there is only a small difference between the surfaces for a given assumed state, indicating that only a small amount of energy is dissipated by shearing between the particles. Thus, even if frictional sliding occurs it will only have a small influence on the macroscopic response, and it is appropriate to assume that an associated flow rule is valid.

During compaction the stress point remains on the yield surface, therefore, following Eq 19:

$$dF = \frac{\partial F}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial F}{\partial S_\alpha} dS_\alpha = 0 \quad (\text{Eq 28})$$

In order to complete the model, evolution laws for the state variables in terms of the stress, strain, and the state of the material are needed. In the models, the state could be described in terms of suitable measures of strain, or alternatively, plastic strains can be considered the state variables. Then Eq 28 becomes:

$$dF = \frac{\partial F}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial F}{\partial E_{ij}^p} dE_{ij}^p = 0 \quad (\text{Eq 29})$$

Combining Eq 29 with Eq 27 gives

$$\Lambda = - \frac{(\partial F / \partial \Sigma_{ij}) d\Sigma_{ij}}{(\partial F / \partial E_{kl}^p) (\partial F / \partial \Sigma_{kl})} \quad (\text{Eq 30})$$

with the individual strain components given by (Eq 27).

To simplify constitutive models, isotropic behavior is often assumed. This consideration dictates the use of mechanical and material descriptions independent of a particular choice of coordinate system. This freedom allows one to use rotation invariant or coordinate system independent quantities in the constitutive model. For the mechanical stress or strain, which are mathematically represented as tensors of the second order, these quantities are the first and second tensor invariants.

The yield function can then be expressed as a function of $\Sigma_e = \sqrt{3/2 S_{ij} S_{ij}}$, the macroscopic von Mises effective stress in the powder aggregate, a form of the second invariant of the macroscopic stress and $\Sigma_m = \frac{1}{3} \Sigma_{kk}$, the mean stress in the powder aggregate, a form of the first invariant of the macroscopic stress. Equation 26 then assumes the form: $F = F(\Sigma_e, \Sigma_m, S_{\alpha}) = 0$.

If appropriate forms for the yield function in terms of the stress and accumulated plastic strain can be found, the above equations can be employed to determine the full constitutive response. In the following sections, different possible forms of the yield function are examined.

Yield Functions from Micromechanical Models. The section "Deformation of Powder Compacts: Experimental Observations" states the nature of the porosity changes as a material densifies. Initially, the porosity is open and distinct necks exist between the contacting particles (stage 1). At high relative densities ($D > 0.9$), the porosity is closed, which is referred to as stage 2. Different forms of micromechanical models have been developed for these two stages. In the stage 1 models, it is assumed that there is no interaction between the deformation zones that form in the vicinity of the different contacts. Analyses of the contact of two isolated bodies can then be used to obtain the appropriate contact law for a given microplasticity model. The macroscopic response is then determined by combining the contributions from each contact. Fleck et al. (Ref 16) employed a perfectly plastic microplasticity model and assumed that the material was isotropic and could be described using a single state variable, which they took to be the relative density, D . This assumption is equivalent to assuming that the material had previously been compacted isostatically to a given density. From their analysis, Fleck et al. (Ref 16) propose an approximate yield function:

$$F = \left(\frac{\sqrt{5} \Sigma_m}{3 P_y} \right)^2 + \left(\frac{5 \Sigma_e}{18 P_y} + \frac{2}{3} \right)^2 - 1 = 0 \quad (\text{Eq 31})$$

where P_y is the yield strength in hydrostatic compression;

$$P_y = 3 D^2 \frac{(D - D_0)}{(1 - D_0)} \sigma_y \quad (\text{Eq 32})$$

where D_0 is the initial dense random packing density, which is generally taken to be 0.64.

The full response can be obtained from Eq 26 to Eq 30 by noting that the densification rate is given by (neglecting elastic volume changes):

$$\dot{D} = - D \dot{E}_{kk}^p \quad (\text{Eq 33})$$

In practice, the matrix material can strain harden as the contact zones deform plastically. Fleck et al. (Ref 16) demonstrate how the effects of strain hardening can be taken into account. A more compact form of model can be obtained by rewriting Eq 31 in the form of Eq 7, that is,

$$F = \bar{\Sigma} - \sigma_y = 0 \quad (\text{Eq 34})$$

where $\bar{\Sigma}$ is an effective stress for the porous material, which is a function of the macroscopic stress and internal geometry described by D . Rearranging Eq 31 then gives:

$$\bar{\Sigma} = \left[\frac{1}{3} \Sigma_c + \sqrt{\frac{1}{4} \Sigma_c^2 + \Sigma_m^2} \right] \frac{(1 - D_0)}{3D^2 (D - D_0)} \quad (\text{Eq 35})$$

For loading conditions on the yield surface, Eq 29 becomes:

$$dF = \frac{\partial \bar{\Sigma}}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial \bar{\Sigma}}{\partial D} dD - d\sigma_y = 0 \quad (\text{Eq 36})$$

Fleck et al. (Ref 16) take σ_y to be the average yield strength in the plastically deforming material, and they define an average internal effective strain increment, $d\varepsilon_e^P$, by equating the internal and external work. Using the current terminology,

$$\Sigma_{ij} dE_{ij}^P = \bar{\Sigma} \Lambda = \sigma_y \Lambda = G(D) \sigma_y d\varepsilon_e^P \quad (\text{Eq 37})$$

where $G(D)$ is the effective volume fraction of plastically deforming material, given by Fleck (Ref 17) as:

$$G(D) = \frac{45}{\sqrt{3}} D^2 \left(\frac{D - D_0}{1 - D_0} \right)^{3/2} \quad (\text{Eq 38})$$

Combining Eq 36, 37, 33, and 18 gives:

$$\Lambda = d\bar{E} = \frac{(\partial \bar{\Sigma} / \partial \Sigma_{ij}) d\Sigma_{ij}}{D(\partial \bar{\Sigma} / \partial D)(\partial \bar{\Sigma} / \partial \Sigma_{kk}) + [h(\sigma_y) / G(D)]} \quad (\text{Eq 39})$$

where $d\bar{E}$ is a macroscopic effective plastic strain increment not to be confused with the von Mises effective strain increment, dE_e . The advantage of this form is that it separates out the effects of geometric and material hardening and it leads to a more compact expression than the relationships proposed by Fleck et al. (Ref 16).

In the development of the above model, two major assumptions were made: the strengths of the contact zones were assumed to be the same in tension and compression, and the material was assumed to be isotropic. It was demonstrated in the section "Deformation of Powder Compacts: Experimental Observations" that the strengths of the contacts are likely to be different in compression and tension, particularly for smooth particles. Also, when a compact is loaded along stress paths other than hydrostatic, the microstructure (the distribution of necks) becomes anisotropic.

Fleck (Ref 17) has proposed a model in which the tensile strength of a contact patch is less than the compressive strength by a factor η . If P_y (Eq 33) is the magnitude of the pressure required to plastically deform a compact, then the magnitude of the hydrostatic tensile stress required to initiate plastic flow is ηP_y . Fitting a quadratic to Fleck's results and adopting the form of expression presented in Eq 34, the following equation is obtained:

$$\begin{aligned} \bar{\Sigma} = & \frac{1}{\eta} \left[\frac{1}{6} \Sigma_c (1 + \eta) + \frac{1}{2} \Sigma_m (1 - \eta) \right. \\ & \left. + \sqrt{\frac{1}{36} \Sigma_c^2 (1 + 7\eta + \eta^2) + \frac{1}{4} \Sigma_m^2 (1 + \eta)^2 + \frac{1}{6} \Sigma_c \Sigma_m (1 - \eta^2)} \right] \\ & \frac{(1 - D_0)}{3D^2 (D - D_0)} \end{aligned} \quad (\text{Eq 40})$$

This expression reduces to Eq 35 when $\eta = 1$. When $\eta = 0$, it becomes:

$$\bar{\Sigma} = - \frac{4\Sigma_m^2 + \frac{5}{9}\Sigma_e^2(1 - D_0)}{4\Sigma_m + \frac{4}{3}\Sigma_e 3D^2(D - D_0)} \quad (\text{Eq 41})$$

The yield surfaces are plotted in Fig. 8 for $\eta = 0$ and 1, where they are compared with the surfaces obtained by Fleck (Ref 17). It should be noted that these surfaces have vertices where they meet the Σ_m axis. The direction of the strain increment vector is nonunique for pure hydrostatic stress states, which can lead to computational difficulties when implementing this model. In practice, this nonuniqueness has been bypassed by inserting a circular arc at the vertex to ensure a smooth continuous yield surface (Ref 19).

(a)

(b)

Fig. 8 Yield surfaces predicted by Fleck's (Ref 17) isotropic model for (a) $\eta = 0$ and (b) $\eta = 1$, compared with the prediction of Eq 41 and 35

Fleck (Ref 17) has also examined the influence of material anisotropy by relating the size and number of contacts at a given orientation to the plastic strain E_{ij}^p . The surface for frictionless closed-die compaction, normalized by the hydrostatic stress, P , required to compact the material to the same density is shown in Fig. 9 for $\eta = 0$, where it is compared with the comparable surface for hydrostatic compaction. There are a number of important points to note:

- The surface for closed-die compaction is extended in the direction of loading and contracted in the transverse direction compared to the surface for hydrostatic compaction. Thus, the yield behavior cannot be described in terms of the relative density alone.
- The vertex on the yield surface is at the loading point. Similar results are obtained for crystal plasticity theory applied to fully dense materials.
- The yield surfaces expand in a self-similar manner. Thus, the different components of stress increase in proportion to each other when the straining is proportional.
- It is not possible to obtain a closed form solution for arbitrary loading paths. Thus, the full micromechanical model is required in order to compute the constitutive response.

The predictions of this model are compared with the experimental results of Akisanya et al. (Ref 10), shown in Fig. 10 for hydrostatic and closed die compaction. It is evident that the general form of these surfaces is well represented by this model.

Fig. 9 Yield surfaces for isostatic and closed-die compaction predicted by the anisotropic model of Fleck (Ref 17)

Fig. 10 Comparison of Fleck's (Ref 17) model with the experimental results of Akisanya et al. (Ref 10)

So far only the early stages of compaction, when distinct necks exist between the particles, have been discussed. In the latter stages of compaction ($D > 0.9$), the pores are isolated. Constitutive models employed in this regime have been taken from studies originally concerned with ductile failure. In these models, the pores are assumed to remain spherical. The most widely used model is developed by Gurson (Ref 20), which predicts a yield surface given by:

$$F = \left(\frac{\Sigma_e}{D\sigma_y} \right)^2 + \frac{2(1-D)}{D^2} \cosh \left(\frac{3\Sigma_m}{2\sigma_y} \right) - \frac{2(1-D)}{D^2} - 1 = 0 \quad (\text{Eq 42})$$

This expression suffers from the same problem as Eq 31, in that the effects of material and geometric hardening are coupled. Cocks (Ref 21) proposed that a more appropriate form for the constitutive model, which does not differ significantly from that proposed by Gurson (Ref 20), is given by Eq 34, with

$$\bar{\Sigma} = \sqrt{\frac{\Sigma_e^2}{G_1(D)} + \frac{\Sigma_m^2}{G_2(D)}} \quad (\text{Eq 43})$$

where

$$G_1(D) = \frac{3D^2}{5-2D} \quad (\text{Eq 44})$$

$$G_2(D) = \left(\ln \left(\frac{1}{(1-D)^2} \right) \right)^2 \quad (\text{Eq 45})$$

Equations 36, 37, 38, and 39 for the constitutive response again apply, where, now, $G(D) = D$.

In practice, the pores do not achieve a spherical shape during the latter stages of compaction. Instead, they maintain a cusp shaped profile. Liu et al. (Ref 22) and Akisanya et al. (Ref 23) have demonstrated that bodies with cusp-shaped pores have greater compressibility than bodies with spherical pores at the same density. Qian et al. (Ref 24) have suggested how the influence of the cusp-shaped pores can be incorporated into the constitutive models for creeping materials. They still assume that the body is isotropic macroscopically. Extending their analysis to a perfectly plastic material would simply result in different definitions of $G_1(D)$ and $G_2(D)$ in Eq 43.

Under general loading situations, the expectation might be that the pores would become squashed in the main direction of compaction. Ponte Castenada (Ref 25) has examined the effect of oriented ellipsoidal-shaped pores on the constitutive response, but there have not been any studies of the influence of distorted cusp-shaped pores on the material behavior. In all the stage 2 models, it has always been assumed that the contact patches between the distorted particles are able to support tensile tractions and the contacting particles are unable to slide over each other. There has been no attempt to analyze the effect of the strength of these contacts on the constitutive response.

The yield surfaces for stage 1 and stage 2 compaction can have different shapes. In order to ensure a smooth transition, a gradual change from one shape to another is assumed to occur over a given range of relative density. Assuming a linear variation from the yield expression for stage 1 to that for stage 2 over the range D_1 to D_2 gives:

$$\bar{\Sigma} = \left(\frac{D_2 - D}{D_2 - D_1} \right) \bar{\Sigma}_1 + \left(\frac{D - D_1}{D_2 - D_1} \right) \bar{\Sigma}_2 \quad (\text{Eq 46})$$

where $\bar{\Sigma}_1$ is the effective stress for stage 1 compaction and $\bar{\Sigma}_2$ is the effective stress during stage 2. In practice, the transition is generally assumed to occur over the range $D_1 = 0.77$ to $D_2 = 0.9$.

Empirical Yield Functions. In the empirical models of powder compaction, the different form of porosity in stage 1 and stage 2 is not considered. Simple continuous expressions for the yield function are developed that satisfy the condition that the material response is incompressible when $D = 1$. The most widely used expressions are those due to Kuhn and Downey (Ref 6) and Shima and Oyane (Ref 7). These models have the same general structure as those described in the section "Yield Functions from Micromechanical Models." The yield function can again be represented in the form of Eq 34. For simplicity, a quadratic function of the von Mises effective stress, Σ_e , and mean stress, Σ_m , is assumed for $\bar{\Sigma}$. It is further assumed that the material response can be described in terms of a single state variable, the relative density, D . $\bar{\Sigma}$ can then be expressed in the form of Eq 43, where $G_1(D)$ and $G_2(D)$ are determined experimentally by assuming that the material yield strength σ_y remains constant. Shima and Oyane (Ref 7) determined these quantities by compacting samples in a closed die to a given density, sintering the samples and then performing uniaxial tensile and compressive tests to determine the yield properties. By measuring the uniaxial yield strength and Poisson's ratio, $G_1(D)$ and $G_2(D)$ could be determined at the chosen density; and by repeating these tests at different densities, the complete functions $G_1(D)$ and $G_2(D)$ could be determined. Their results for copper and iron powders are well approximated by:

$$G_1(D) = D^5 \quad (\text{Eq 47})$$

$$G_2(D) = \frac{D^5}{6.25(1-D)} \quad (\text{Eq 48})$$

The above form has been employed by a number of authors in experimental and computational studies of powder compaction. Kim and Suh (Ref 26) recognized that a material could harden as a result of shear deformation as well as a result of densification. They proposed a modified form of expression for the yield function:

$$F = \bar{\Sigma} - \kappa = 0 \quad (\text{Eq 49})$$

with

$$\bar{\Sigma} = \sqrt{\Sigma_e^2 + 1.2(1 - D)\Sigma_m^2} \quad (\text{Eq 50})$$

Here κ is the effective yield strength of the compact. The evolution law for κ is assumed to be of the form:

$$d\kappa = \beta_1 \sigma_e d\varepsilon_e + \beta_2 \sigma_m d\varepsilon_{kk} \quad (\text{Eq 51})$$

which takes into account geometric and material hardening. Now, from Eq 28 and 51, find:

$$\Lambda = \frac{(\partial \bar{\Sigma} / \partial \Sigma_e) d\Sigma_e + (\partial \bar{\Sigma} / \partial \Sigma_m) d\Sigma_m}{D (\partial \bar{\Sigma} / \partial D) (\partial \bar{\Sigma} / \partial \Sigma_m) + \beta_1 (\partial \bar{\Sigma} / \partial \Sigma_e) \Sigma_e + \beta_2 (\partial \bar{\Sigma} / \partial \Sigma_m) \Sigma_m} \quad (\text{Eq 52})$$

and the individual plastic strain increments are given by Eq 27. The yield function of Eq 49 was found to give a slightly better fit of the tension/torsion experiments of Kim et al. (Ref 5) on sintered iron compacts discussed earlier than the model of Shima and Oyane (Ref 7).

These models were validated by performing experiments on sintered compacts. The effect of the sintering process is to anneal the particles and to bond them together. As a result, the yield strength is expected to be the same in tension and compression, as observed by Shima and Oyane (Ref 7), and it is not unreasonable for a quadratic function, such as those presented in Eq 43 and 50, to adequately describe the shape of the yield surface. A consequence of this choice of yield function is that it will always predict a negative volumetric strain-rate when the mean stress is negative (i.e., compaction will always occur under net compressive stress states). In experiments on compacted, but not sintered, powders, Brown and Abou-Chedid (Ref 27) and Watson and Wert (Ref 9) observed that the volumetric strains were positive in uniaxial compression.

Based on their experimental observations, Watson and Wert (Ref 9) proposed the adoption of Drucker and Prager's (Ref 28) two part yield surface, which has been employed to model the response of soils. This surface is shown schematically in Fig. 11 and consists of a shear surface and a spherical cap. Watson and Wert (Ref 9) assumed associated flow for both surfaces (i.e., the strain-increment vector is normal to the surface). Thus, dilation occurs for stress states on the shear surface and compaction occurs if the loading point lies on the spherical cap.

Fig. 11 Schematic of Watson and Wert's (Ref 9) two surface Drucker-Prager model

Following Gurson and McCabe (Ref 29), Brown and Abou-Chedid (Ref 27) proposed a modified form of the Cam-Clay model (Ref 30, 31) to model their experiments. In this model the yield surface is represented by Eq 34, with

$$\bar{\Sigma} = \sqrt{A(D)\Sigma_e^2 + B(D)(\Sigma_m - C)^2} \quad (\text{Eq 53})$$

Brown and Abou-Chedid (Ref 27) did not propose forms for the functions $A(D)$ and $B(D)$. More detailed experiments are required to determine the exact form of these expressions.

The macroscopic effective stress of Eq 53 is similar to the quadratic forms of Eq 43 and 50, but now the elliptic surface is centered on the point $(0, C)$ in $\Sigma_e - \Sigma_m$ space. The quantity C represents the degree of cohesion between the particles. If they are perfectly bonded, $C = 0$, and the surface reduces to the symmetric expressions of Eq 43 and 50, which is appropriate for sintered materials. If the particles are smooth and the contacts are unable to support a normal tensile stress, then the value of C can be chosen so that the yield surface passes through the origin, as in the micromechanical model of Eq 41 for $\eta = 0$. Then,

$$C = -\frac{\Sigma}{(B(D))^{1/2}} \quad (\text{Eq 54})$$

and Eq 53 becomes

$$\bar{\Sigma} = -\frac{A(D)\Sigma_e^2 + B(D)\Sigma_m^2}{2(B(D))^{1/2} \Sigma_m} \quad (\text{Eq 55})$$

Equation 55 is equivalent to the most common form of Cam-Clay model used to evaluate the response of soils (Ref 31).

These last two models were derived from constitutive laws that have been developed for soils. A wide range of models have been proposed in the literature for granular materials, in which the yield surfaces are allowed to adopt different shapes, as well as being able to translate in stress space, in a similar manner to the kinematic models (Ref 31).

A Constitutive Model for Metallic Powders with Ductile Particles

Several constitutive models have been applied to the numerical simulation of powder compaction in dies. The most widely used are variations of two types of models: models with an empirical quadratic yield function (Ref 32, 33, 34, 40, and 41) and Cap models (Ref 35, 36, 38, and 39).

The main practical advantages of a model of the first type as developed in Ref 34, 36, 40, and 41 include:

- A reasonable representation of the behavior of metal powders with ductile particles under monotonic loading
- A continuous yield function that facilitates its numerical implementation
- Experimental calibration with a relatively small number of tests

Furthermore, this model has been implemented in the compaction modeling finite element code PCS (Ref 42) that is in use by several parts manufacturers in the United States. The overall strategy presented here can be employed for any of the models described in the section "Constitutive Models for Metal Powder Compaction." The only difference lies in the range of experiments that need to be performed in order to determine any unknown functions in the models.

Model Formulation

The model considered in detail here uses an empirical yield function and fits the general framework presented earlier with assumptions:

- As the powder aggregate is compacted, the particles deform plastically according to the behavior described by classical plasticity with isotropic hardening
- The powder compact displays macroscopic elastic-plastic behavior that is isotropic and independent of strain rate
- The total strain can be decomposed into elastic and plastic components
- The contributions of particle sliding to the overall deformation are negligible
- The state of the powder aggregate is represented by two state variables, the relative density, D , and the yield strength of the powder particle σ_y

Rigorously, for elastic-plastic models, a slightly different definition of the relative density D is necessary when D is used as a state variable. Earlier D was defined as the ratio of the density of powder to the density of the fully dense material. However, the plastic state of the material should not be affected by the changes in D that are due to elastic deformation. A more appropriate definition of D is the ratio of the density of unloaded powder to the density of the fully dense material, the relaxed relative density of the powder aggregate.

Following the general approach presented earlier, consider an element of a powder compact, which is subjected to a macroscopic stress state σ_{ij} and experiences strains E_{ij} . The strain can be decomposed into macroscopic elastic and plastic components as per Eq 21:

$$E_{ij} = E_{ij}^e + E_{ij}^p \quad (\text{Eq 56})$$

Here assume that the elastic response is isotropic. The elastic constitutive law can then be expressed by Eq 22:

$$E_{ij}^e = E_{ij}^{ed} + \frac{1}{3} E_v^e \delta_{ij} = \frac{S_{ij}}{2G} + \frac{\Sigma_m}{3K} \delta_{ij} \quad (\text{Eq 57})$$

where G and K are functions of D .

An empirical yield function F of the general form of Eq 26, which is a function of the stress state and two state variables, is given by:

$$F = F(\sigma_e, P, \sigma_y, D) = 0 \quad (\text{Eq 58})$$

where $P = -\frac{1}{3} \sigma_{kk} = -\frac{1}{3} \sigma_m$, is the pressure, a form of the first invariant of the macroscopic stress.

The specific form of the yield function is as defined in Eq 34 and 43:

$$F = \frac{\Sigma_e^2}{G_1(D)} + \frac{P^2}{G_2(D)} - \sigma_y^2 = 0 \quad (\text{Eq 59})$$

As the powder aggregate densifies and reaches high relative density, its response will approach the incompressible plastic behavior of fully dense metals. Therefore, the function $G_1(D)$ is expected to increase monotonically with an increase in relative density and the function $G_2(D)$ is expected to decrease monotonically with an increase in relative density.

The yield functions developed by Trasorras et al. (Ref 34) involved functions $b(D)$ and $c(D)$ that are expressible in terms of the functions $G_1(D)$ and $G_2(D)$ in the following manner: $G_1(D) = c(D)$ and $G_2(D) = 3c(D)/2b(D)$.

In the following development, the yield function is cast in the form used in Ref 34.

$$F = \Sigma_e^2 + \frac{3}{2} b(D) P^2 - c(D) \sigma_y^2 = 0 \quad (\text{Eq 60})$$

The functions $b(D)$ and $c(D)$ are to be determined through experiments.

The associated flow at the macroscopic level (from Eq 27) yields:

$$\begin{aligned} dE_{ij}^p &= d\Lambda \frac{\partial F}{\partial \Sigma_{ij}} = d\Lambda \left[\frac{\partial F}{\partial \Sigma_e} \frac{\partial \Sigma_e}{\partial \Sigma_{ij}} + \frac{\partial F}{\partial P} \frac{\partial P}{\partial \Sigma_{ij}} \right] \\ &= 3d\Lambda \left[S_{ij} - \frac{1}{3} P b(D) \delta_{ij} \right] \end{aligned} \quad (\text{Eq 61})$$

From Eq 61, the volumetric and deviatoric components of the plastic strain are given by:

$$dE_v^p = -d\Lambda \frac{\partial F}{\partial P} = -3d\Lambda P b \quad (\text{Eq 62})$$

$$dE_e^p = d\Lambda \frac{\partial F}{\partial \Sigma_e} = 2\Sigma_e d\Lambda \quad (\text{Eq 63})$$

Eliminating $d\Lambda$ allows

$$dE_v^p \frac{\partial F}{\partial \Sigma_e} + dE_c^p \frac{\partial F}{\partial P} = 0 \quad (\text{Eq 64})$$

The conservation of mass is expressed in the form of the continuity equation (from Eq 33):

$$\dot{D} = -D \dot{E}_{kk}^p \quad (\text{Eq 65})$$

On integration, the continuity equation yields the following result for the evolution of relaxed relative density,

$$D = D_0 \exp(-E_{kk}^p) \quad (\text{Eq 66})$$

The isotropic hardening law for the powder particle (from Eq 18) is:

$$d_y = h d\varepsilon_e^p \quad (\text{Eq 67})$$

The particle hardening h may be constant (isotropic linear hardening), or may be a function of equivalent plastic strain in the particle.

If the energy dissipated by particle sliding is negligible, as assumed earlier, the external and internal plastic work of deformation can be equated (from Eq 37 with $G(D) = D$):

$$\Sigma_{ij} dE_{ij}^p = D \sigma_y d\varepsilon_e^p \quad (\text{Eq 68})$$

Application to Powder Blends

In the previous sections, the constitutive models have assumed that the powder consists of an aggregate of metal particles of a single kind. In powder compaction in dies, the powder blend will contain lubricant, and in the case of ferrous alloys, often graphite and other alloying elements as well. The theories presented here are expected to be valid for powder blends, provided that the additions to the base metal powder occupy a small volume of the total aggregate (typically a few volume percent). That being the case, the models can be used with the constraints that:

- The relative density D be defined as the ratio of the total density of the powder to the pore-free density of the powder to enforce a plastically incompressible behavior when the material reaches the pore-free density, as opposed to the density of the fully dense metal particle.
- The elastic properties, which are strongly dependent on the presence of nonmetallic constituents, be determined experimentally for the specific blend.
- The constitutive functions $b(D)$ and $c(D)$ be experimentally determined for the specific blend.

Experimental Determination of Powder Material Constitutive Properties and Functions

In this section, the experimental procedures that can be applied to determine the constitutive parameters that appear in the model of the preceding section are presented. Techniques used to determine the elastic parameters and the form of the yield function have been described in the section "Deformation of Powder Compacts: Experimental Observations."

Triaxial Tests

A brief description of the triaxial test and apparatus is presented in this section. For a more detailed treatment of the test, stemming from a soil mechanics perspective, see Ref 31. The triaxial test is important as it provides a convenient means of examining a variety of situations involving different ratios of the deviatoric and hydrostatic stress measures. A schematic of the triaxial test cell is shown in Fig. 12. The powder is placed in a container with a flexible wall, typically made of an elastomer, and immersed in a fluid under a pressure, p . Take care not to confuse this notation for the magnitude of fluid pressure with the one used elsewhere for the hydrostatic component of stress (P). A ram at the top of the apparatus provides a means of increasing the axial load on the powder while maintaining fluid pressure. Knowledge of the cell pressure as well as the applied ram load allows for the calculation of the resulting axial stress in the test sample. In addition, appropriate instrumentation on the apparatus ensures measurement of axial and radial dimensional changes. These measurements can then be translated into axial and radial strains. With the added assumption of a uniform stress state in the specimen and isotropic behavior of the material, it is reasonable to conclude that the radial and tangential strains, as well as radial and tangential stresses, are equal. Macroscopically, the stress state of the powder can be stated as:

$$\Sigma_z = - \left[\frac{F}{A} + p \left(1 - \frac{a}{A} \right) \right] \quad (\text{Eq 69})$$

$$\Sigma_r = -p \quad (\text{Eq 70})$$

Fig. 12 Triaxial compaction cell. Source: Ref 31

The quantities A and a are the areas of cross section of the specimen and ram, respectively. The strains are calculated as:

$$E_r = \ln \left(\frac{r}{r_0} \right) \quad (\text{Eq 71})$$

$$E_z = \ln \left(\frac{l}{l_0} \right) \quad (\text{Eq 72})$$

where r_0 and l_0 are, respectively, the initial radius and length of the compact, and r and l , the current values of these quantities. The deviatoric and hydrostatic components of stress reduce to:

$$\Sigma_e = \sqrt{\frac{3}{2} S_{ij} S_{ij}} = \Sigma_r - \Sigma_z \quad (\text{Eq 73})$$

$$P = -\frac{1}{3}(2\Sigma_r + \Sigma_z) \quad (\text{Eq 74})$$

In soil mechanics, triaxial tests are often performed in one of three ways, as depicted in Fig. 13. The first, the isostatic compaction test, is used to characterize soils under hydrostatic loading and to determine the elastic bulk modulus. In this test, the ram load is maintained insofar as to ensure a hydrostatic state of stress in the test specimen. The second test, the consolidated triaxial test, involves initial pressurization of the test cell followed by an increase in ram load, the cell pressure being maintained constant. The path of stress on the P - Σ_e plane has a slope of 3 as the axial load increases at constant confining pressure. This path can be verified by taking the derivatives of the expressions for P and Σ_e while keeping p constant, and then calculating the slope using the ratio of the derivatives. Finally, the overconsolidated tests are employed to help determine the shape of the yield surface on the P - Σ_e plane. The test consists of subjecting the specimen to a history of deformation under pure pressure, following this by unloading to an intermediate pressure, and subsequently increasing the ram load while maintaining cell pressure to determine a different point on the yield surface.

Fig. 13 Stress paths in isostatic compaction test, consolidated triaxial compaction test, and overconsolidated compaction test. Source: Ref 43

As presented in the section "Deformation of Powder Compacts: Experimental Observations," the size and shape of the yield surface are functions of the history of loading. Thus, if the strain history only involved hydrostatic loading, subsequent probing of the yield surface in the manner of an overconsolidated triaxial test will only identify a yield surface defined by this initial loading. A different picture will emerge if the yield surface is identified following a stress path, such as the one used in a consolidation test, followed by unloading and subsequent probing of the yield surface (Fig. 3). This is of particular importance when considering tests to be used for material parameter extraction; the best tests shall be those involving stress paths as close to the real situation as possible. In the case of compaction in dies, the compact is constrained radially. The triaxial test setup should then include control of cell pressure to ensure zero radial strain in the sample to simulate actual compaction conditions.

Calibration of Material Parameters for an Iron Powder Blend

The procedures of the previous section are applied below to the calibration of the two-state variable model introduced earlier. The data is for a powder blend comprising 99.5% by weight of Distalloy AE, 0.5% by weight of graphite, and 1% wax Hoechst micropulver. This last component is admixed as internal lubricant. Distalloy AE is a diffusion alloyed iron powder with composition 4 wt% Ni, 1.5 wt% Cu, and 0.5 wt% Mo. Particle sizes for this powder range from 20 to 180 μ

m. The apparent density of the powder is 3.04 g/cm^3 ; the pore free density of the material is 7.33 g/cm^3 . The data used are from experiments reported by Pavier and Doremus (Ref 14).

Consider the yield function of the model introduced in the section "A Constitutive Model for Metallic Powders with Ductile Particles" :

$$F = \Sigma_e^2 + \frac{3}{2} b(D) P^2 - c(D) \sigma_y^2 = 0$$

To fully determine the yield function F the functions $b(D)$ and $c(D)$ must be identified. Figure 14 illustrates the yield surface for a lubricated atomized iron powder (Hoeganaes Ancorsteel 1000). The surface is plotted for different values of relative density and particle yield stress pairs. For this powder, the functions $b(D)$ and $c(D)$ were determined by Trasorras et al. (Ref 40) to be:

$$b(D) = \frac{0.13 D^{-5.6}}{(D + 0.62)^{1.35}} \quad (\text{Eq 75})$$

$$c(D) = D^6 \quad (\text{Eq 76})$$

The constitutive model has two-state variables and requires two different kinds of tests for its calibration.

Fig. 14 Yield surface for lubricated atomized iron powder (Hoeganaes Ancorsteel 1000). Surface plotted for different values of relative density and particle hardening

Triaxial Consolidation Test for $b(D)$. The state of stress in the test specimen is assumed to be uniform throughout (homogeneous). This assumption leads to the result that the radial Σ_r and tangential Σ_z stresses are equal and given by the cell pressure. If the specimen is cylindrical in shape, the components of stress in the powder aggregate can then be appropriately defined using a cylindrical coordinate system as follows:

$$[\Sigma] = \begin{bmatrix} -\Sigma_r & 0 & 0 \\ 0 & -\Sigma_r & 0 \\ 0 & 0 & -\Sigma_z \end{bmatrix} \quad (\text{Eq 77})$$

The negative signs are assigned to indicate the compressive nature of the stresses in the aggregate. The deviatoric and pressure components are then:

$$P = -\frac{1}{3}(-\Sigma_r - \Sigma_r - \Sigma_z) = \frac{1}{3}(2\Sigma_r + \Sigma_z) \quad (\text{Eq 78})$$

$$S = \Sigma + PI = \begin{bmatrix} -\frac{1}{3}\Sigma_r + \frac{1}{3}\Sigma_z & 0 & 0 \\ 0 & -\frac{1}{3}\Sigma_r + \frac{1}{3}\Sigma_z & 0 \\ 0 & 0 & \frac{2}{3}\Sigma_r - \frac{2}{3}\Sigma_z \end{bmatrix} \quad (\text{Eq 79})$$

Calculating $\Sigma_e = \frac{3}{2} \sqrt{S_{ij}S_{ij}}$, find

$$\Sigma_e^2 = \frac{3}{2} \left(\frac{2}{9} (\Sigma_z - \Sigma_r)^2 + \frac{4}{9} (\Sigma_r - \Sigma_z)^2 \right) \quad (\text{Eq 80})$$

$$\Sigma_e = \sqrt{(\Sigma_z - \Sigma_r)^2} \quad (\text{Eq 81})$$

The increment of plastic strain given by Eq 61 is:

$$\begin{aligned} \Delta E_r^p &= 3\Delta\Lambda \left[\frac{1}{3}(\Sigma_z - \Sigma_r) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \\ \Delta E_\theta^p &= 3\Delta\Lambda \left[\frac{1}{3}(\Sigma_z - \Sigma_r) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \\ \Delta E_z^p &= 3\Delta\Lambda \left[\frac{2}{3}(\Sigma_r - \Sigma_z) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \end{aligned} \quad (\text{Eq 82})$$

The deviatoric and volumetric components of plastic strain increment become:

$$\Delta E_v^p = 3\Delta\Lambda \left[-\frac{1}{3}(2\Sigma_r + \Sigma_z)b(D) \right] \quad (\text{Eq 83})$$

$$\Delta E_z^p - \Delta E_r^p = -3\Delta\Lambda(\Sigma_z - \Sigma_r) \quad (\text{Eq 84})$$

Eliminating $\Delta\Lambda$ obtain,

$$\frac{\Delta E_v^p}{\Delta E_z^p - \Delta E_r^p} = \frac{b(D)(2\Sigma_r + \Sigma_z)}{3(\Sigma_z - \Sigma_r)} \quad (\text{Eq 85})$$

Solving for $b(D)$,

$$b(D) = \frac{3(\Sigma_z - \Sigma_r)\Delta E_v^p}{(2\Sigma_r + \Sigma_z)(\Delta E_z^p - \Delta E_r^p)} \quad (\text{Eq 86})$$

Thus, the function $b(D)$ may be determined using data from the triaxial tests for values of axial stress Σ_z , axial plastic strain increment ΔE_z^p , and radial strain increment ΔE_r^p corresponding to a range of values of cell pressure Σ_r .

The results of applying Eq 86 to the experimental data of Pavier and Doremus (Ref 14) for the Distalloy AE blend are shown in Fig. 15. Because noise is inherently present in such information, a cursory smoothing using a moving average scheme was performed prior to computing the increments of strain. In addition, the elastic components of strain were

assumed to be negligible. For low relative densities, this assumption is reasonable. However, as plastic incompressibility is approached, the validity of the assumption must be checked. A curve fit for $b(D)$ results in the following expression:

$$b(D) = \frac{1}{2.8287} \ln \left(\frac{7.6 - 7.33D}{0.2516} \right) \quad (\text{Eq 87})$$

Fig. 15 Function $b(D)$ for an iron powder blend comprising 99.5% by weight Distalloy AE, 0.5% by weight graphite, and 1% wax Hoechst micropulver

Isostatic Compaction Test for $c(D)$. The state of stress in the isostatic compaction test is one of pure pressure, with no shear or deviatoric stress present. The isotropic test provides a convenient means of evaluating the evolution of relative density as a function of increasing cell pressure. Data are obtained by increasing cell pressure to a point before unloading the cell to determine the resulting powder relative density. Following Pavier and Doremus (Ref 14), the relation between the relative density for the powder under hydrostatic loading and the applied pressure or hydrostatic stress was determined to be:

$$P_y = \frac{37.596}{1.0364 - D} - 46.2976 \quad (\text{Eq 88})$$

where P_y is expressed in MPa and represents the pressure at yield given a value of relative density, D in the isostatic test.

It is reasonable to assume that the material is continuously yielding with load. Further, since shear stress is completely absent, Eq 60 reduces to:

$$F = \frac{3}{2} P_y (D)^2 b(D) - \sigma_y^2 c(D) = 0 \quad (\text{Eq 89})$$

If particle hardening is considered, the calculation of $c(D)$ involves the simultaneous integration of partial differential equations for the evolution of particle yield stress and the functions $b(D)$ and $c(D)$. However, for simplicity, assume the powder particles are perfectly plastic and obtain $c(D)$ from (Eq 89):

$$c(D) = \frac{3P_y (D)^2 b(D)}{2\sigma_y^2} \quad (\text{Eq 90})$$

Using the forms for pressure and $b(D)$ from Eq 88 and 87, and assuming a mean value of 375 MPa for particle yield stress, the function $c(D)$ is calculated and plotted in Fig. 16.

Fig. 16 Functions $b(D)$ and $c(D)$ for a iron powder blend comprising 99.5% by weight Distalloy AE, 0.5% by weight graphite, and 1% wax Hoechst micropulver

Verification of Calibrated Model. This section evaluates the accuracy of the calibration performed for functions $b(D)$ and $c(D)$ for the Distalloy AE blend considered using triaxial test data. Analysis data were generated through a finite element simulation of the triaxial tests conducted. Because hardening of the powder particles is a likely event, it is considered here. Specifically, the material of the powder particle was modeled as having a yield stress of 250 MPa with a hardening of 333 MPa. These values were obtained from data reported by Trasorras et al. (Ref 36). Figure 17 shows a comparison of the predicted powder density as it evolves during the triaxial tests against data measured by Pavier et al. (Ref 14). There is very good agreement between simulation and experiment. Figure 18 shows a plot of axial strain versus radial strain for a triaxial cell pressure of 250 MPa. The strains are measured relative to the onset of shear in the specimen, marked by an increase in axial stress over the cell pressure. Figure 19 shows a plot of axial stress versus axial strain for the same triaxial cell pressure of 250 MPa. Again, the simulations compare well with the experiments.

Numerical Modeling of Powder Compaction in Dies

In this section, practical illustrations of finite element analysis of powder compaction are presented. The first one is the compaction of a two-level component with emphasis on the effect of compaction kinematics on punch loads. The second example, the compaction of a long bushing, illustrates density predictions.

Compaction of a Two-Level Part

The model presented in the section "A Constitutive Model for Metallic Powders with Ductile Particles" is used to examine the compaction of an axisymmetric two-level component. This part was studied experimentally by Kergadallan et al. (Ref 4). The part was pressed with five different tooling motions; two of those cases, labeled as part 30 and part 34, are presented here. The compaction experiments and the finite element model are described, and numerical predictions are compared to experimental results.

Compaction Experiments. Following are the conditions of the compaction tests used to study an axisymmetric two-level component.

Part Geometry. The part is axisymmetric with a thin outer rim, a hub, and a bore. This geometry is representative of many common powder metal parts (e.g., engine camshaft timing pulleys, one-way mechanical diode clutch plates). Geometry and dimensions are shown in Fig. 20. The outer diameter is 78 mm and the overall height is 26 mm.

Fig. 20 Nominal dimensions of axisymmetric part used in compaction experiments

The powder blend is based on the diffusion alloyed iron powder, Hoeganaes Distalloy AE, as described in section "Calibration of Material Parameters for an Iron Powder Blend."

Press and Tooling. Figure 21 shows a schematic of the press and tooling. The part was pressed in a hydraulic COSMO press. The tooling consists of four moving components: an outer die and an inner core that move together, a top punch, and a lower inner punch. The tooling also includes a stationary lower outer punch. The press was instrumented with strain gauges to measure loads on tooling members (see Fig. 21) and potentiometer displacement transducers to measure tooling displacements.

Fig. 21 Schematic of hydraulic COSMO press, tooling and strain gauges for load measurement. Source: Ref 4

Initial Conditions. The fill positions of the punches are given by R_1 and R_2 as shown in Fig. 22 and Table 2. The initial density in the die cavity was estimated by assuming uniform density within the rim section and the hub section of the part, as shown schematically in Fig. 23. The initial density values (Table 2) were estimated by weighing the different sections of the part and assuming no mass transfer between the top and bottom sections.

Table 2 Initial conditions for two-level compaction experiments

Conditions	Part 30	Part 34
Rim fill (R_1), mm	54.71	55.82
Hub fill (R_2), mm	27.23	25.18
ρ_{Hub} , g/cm ³	3.51	3.63
ρ_{Rim} , g/cm ³	3.21	2.97
Mass, g	498.09	482.42

Fig. 22 Actual tooling motions for axisymmetric component with piecewise linear approximations. Source: Ref 4

Fig. 23 Estimated initial fill density distribution for parts used in compaction experiments. Source: Ref 4

Compaction Kinematics. The displacement histories for each of the moving tooling members are shown in Fig. 22. Tabulated information on punch displacements for part 30 and part 34 can be found in Ref 4. As explained later in this section, compaction of part 30 results in low density in the rim section. Also, cracks appear on the inner and outer surface of the rim. The aim of the compaction kinematics used with part 34 was to reduce the density imbalance between the hub and rim sections and to eliminate the cracks.

The Finite Element Model. The powder material model described in the section "A Constitutive Model for Metallic Powders with Ductile Particles" was implemented in the finite element code Abaqus/Standard (Ref 2) through a user-defined material subroutine. Details of the numerical implementation are beyond the scope of this article. Aravas (Ref 3) has described the numerical integration of constitutive models of this class.

Finite Element Model. An axisymmetric model of the compact was set up using four noded axisymmetric elements (Ref 2). Figure 24 shows a three-dimensional representation of the finite element mesh obtained by revolving the part about the axis of symmetry.

Fig. 24 Three-dimensional representation of the axisymmetric finite element discretization of the powder compact

Tooling. For simplicity, the tooling components were modeled as rigid surfaces. In a more detailed model, the tooling can also be modeled assuming elastic material behavior. Tooling stresses can be computed this way. However, modeling the interfaces between the powder and the elastic tooling is numerically very intensive.

Material Model. Constant values were used for the elastic properties. A fixed value of Young's modulus (141 GPa), corresponding to the final average density, was calculated using the expression for elastic modulus determined by Pavier et al. (Ref 14). It was mentioned earlier that the elastic properties are strong functions of density. However, in an analysis such as this, severe numerical instabilities can result as a consequence of the soft elastic properties at low density. Further, the effect of elastic behavior is dominant only when the relative density approaches its pore-free value.

The friction coefficient between iron powder compacts and steel/carbide tooling varies with the normal stress (Ref 44, 45). For lubricated iron powders, the coefficient of friction varies in the range 0.1 to 0.2 for normal stresses in the range 100 to 700 MPa. For the present model, a Coulomb friction model was used and a coefficient of friction of 0.15 was assumed.

Compaction Kinematics. A piecewise linear approximation to the actual tooling motions was used as depicted in Fig. 22.

Part Fill Density. The initial fill density was set as represented schematically in Fig. 23.

Experimental and Modeling Results. Figure 25 shows the compaction forces measured for part 30. The forces exerted on the bottom and upper punches increase from the initial instant corresponding to the moment of contact between the powder and the upper punch. At instant t_{L1} (Fig. 22), the speed of the lower inner punch (LIP) is modified such that it descends at practically constant force over the rest of its travel through time t_{L2} . While the LIP is in motion, the upper punch (UP) and the lower outer punch (LOP) withstand forces that increase progressively up to their peak values. The rest of the cycle, for time $>t_{L2}$, continues while the LIP remains at a fixed position. The forces on the LOP and the UP increase rapidly to their maximum values. Compression finishes at time t_F , corresponding to the maximum displacement of the UP. The maximum loads recorded are shown in Table 3. Densities were measured in five sections of the part as shown schematically in Fig. 26. Measurements are shown in Table 4. For part 30, the hub and rim densities are approximately 7.06 g/cm^3 and 6.90 g/cm^3 .

Table 3 Measured and computed peak compaction loads

Punch	Part 30 loads, MN		Part 34 loads, MN	
	Measured	Predicted	Measured	Predicted
LIP	2.10	2.12	1.61	1.75
LOP	0.59	0.36	0.61	0.5

Table 4 Measured sectional densities

Section of Fig. 26	Density, g/cm^3	
	Part 30	Part 34
1	7.01	6.9
2	7.07	6.93
3	7.09	7.03
4	6.90	6.91

Fig. 25 Comparison of compaction tooling loads for part 30: predicted versus experimental

Fig. 26 Comparison of compaction tooling loads for part 34: predicted versus experimental

After ejection, the parts were visually inspected for cracks. Part 30 presented a distinct crack around the rim ID, 2 mm below the hub. Very fine cracks were also present on the outer surface of the rim, close to the bottom end. Although it is not possible to state exactly when the cracks were formed, it is very likely that they appeared during load removal/ejection. For part 30, the maximum loads on the inner and outer lower punches are 2.1 MN and 0.59 MN, respectively. The high load on the lower inner punch results in high punch deflection. During ejection, the elastic recovery of the lower inner punch results in tension on the rim causing cracking.

To eliminate the cracks that appeared in part 30, part 34 was pressed with higher fill in the rim section and reduced fill in the hub section (Table 2). The tool motions applied were modified to accommodate the different fill positions, otherwise they were very similar to the motions used with part 30. The forces measured are shown in Fig. 27. The peak load values are given in Table 3. The load patterns for parts 30 and 34 are similar; however, for part 34, the lower inner punch load is reduced to 1.61 MN, while the outer lower punch force increases slightly to 0.61 MN. The hub and rim densities are approximately 6.97 g/cm^3 and 6.94 g/cm^3 (Table 3). The reduced load in the lower inner punch results in lower deflection and eliminates tension during load removal/part ejection. Part 34 was defect free.

Fig. 27 Schematic of sections for density measurements for test parts

Figure 28 illustrates the compaction process as predicted by the numerical model. The deformed mesh is plotted for part 34. The model shows that there is very limited transfer of powder between the top and bottom (rim) sections of the part. This behavior is expected because the tooling motions were designed to minimize powder transfer to avoid the formation of a defect at the corner between the two sections. Figure 29 plots the evolution of density in the compact during pressing of part 34.

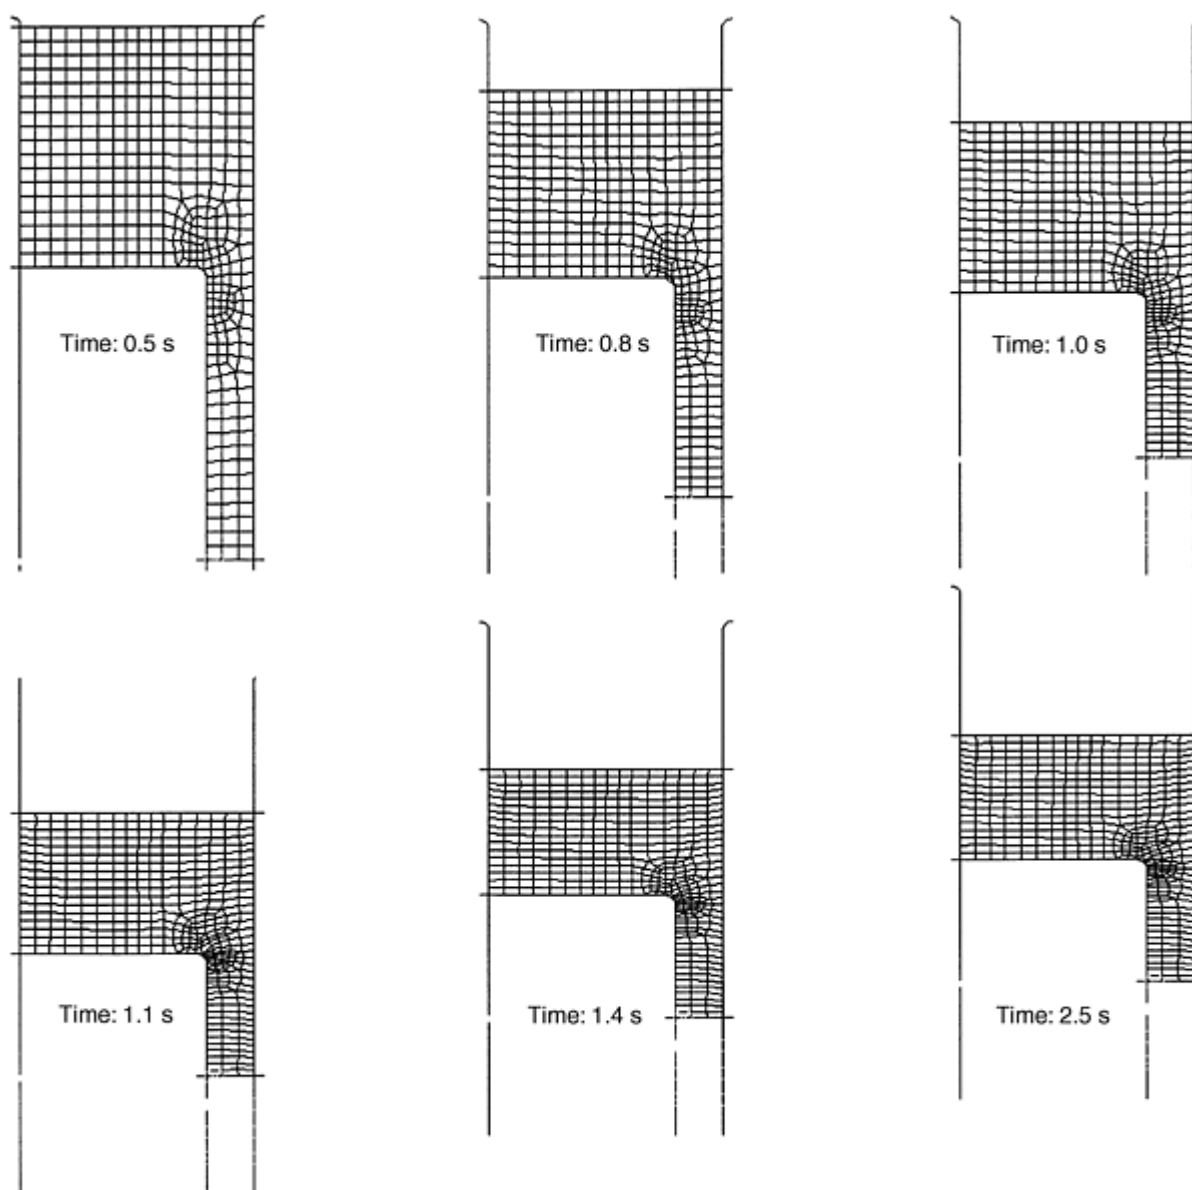

Fig. 28 Deformed mesh during stages of compaction of part 34

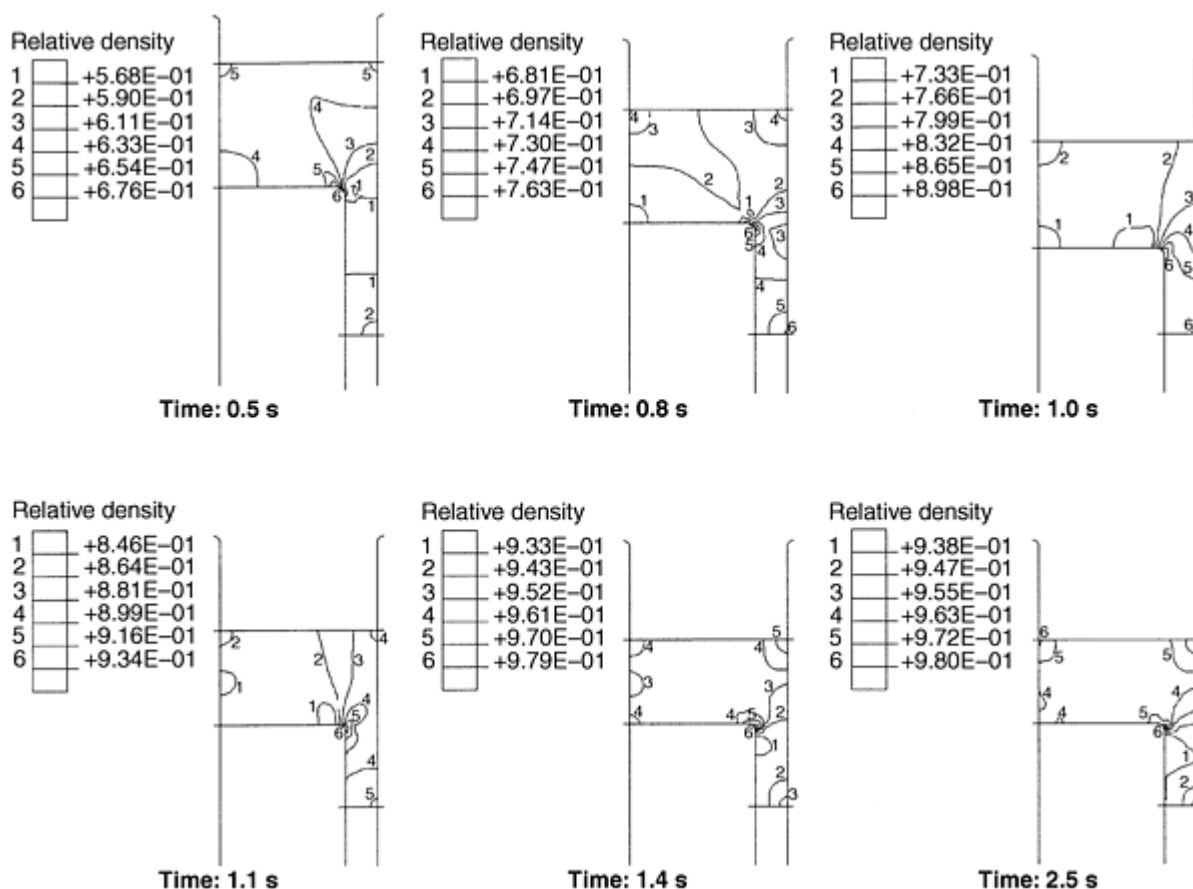

Fig. 29 Computed density fields at different stages of compaction of part 34

The loads computed for parts 30 and 34 are plotted in Fig. 26 and 27 and compared to the measured loads. There is good overall agreement between the experiments (Ref 4) and the calculations. The computed maximum load values for each punch are shown in Table 3. Again the agreement with the experiments is very good, showing that the model is capable of predicting the effects of punch kinematics and fill position on punch loads.

One observation on the nature of the load computations is pertinent. As the compact approaches its pore-free density, it becomes incompressible. Consequently, towards the end of the compaction stroke, minor variations in tool motions result in sharp changes in load. Thus, it is very important to ascertain the exact displacements of tooling members from their reference positions if accurate load predictions are sought.

Compaction of a Long Bushing

This example illustrates how the numerical model can be applied to predict density distributions. This part was studied experimentally by Trasorras et al. (Ref 40). A steel bushing was pressed in a 150 ton mechanical press. The green bushing dimensions are outside diameter (OD) = 19.05 mm, inner diameter (ID) = 12.7 mm, and height = 25.4 mm. The powder used was a blend of atomized steel powder (Ancorsteel 1000) with 0.75 wt% zinc stearate as lubricant. The punch motions comprise the following sequence. After powder filling, the top punch moves down to compact the powder, then rises and exits the die cavity. At the end of top punch motion, the die is stripped to eject the compact. Finally, the core rod is stripped. The lower punch and the die remain stationary throughout the compaction. As compaction starts, a density gradient develops in the bushing due to the friction between the compact and the tooling members. With continued top punch motion, the bushing densifies with the top always being at a higher density than the bottom. During ejection, there is some additional densification of the bottom end of the compact. Finally, the compact expands as it exits the die cavity thereby reducing the overall density. The axial density distribution in the bushing was determined by successively sectioning and weighing the compact.

Compaction of the bushing was modelled in PCS (Ref 42), a powder compaction modeling system based on the finite element code NIKE2D (Ref 46). Figure 30 shows the finite element discretization of the tooling and powder, with the punches shown at their fill position. The material model described earlier was used with the constitutive functions $b(D)$, $c(D)$, and elastic properties calibrated for the atomized iron powder. The initial apparent density of the powder was 3.2 g/cm^3 . A complete model of the tooling was used (Fig. 30) and elastic isotropic behavior was assumed. The friction between the compact and the tooling members was assumed to follow Coulomb's model with a friction coefficient of 0.2. Figure 31 compares the axial density distribution predicted by the numerical model with the experimental results. The model properly represents the densification that takes place during both compaction and ejection and the predicted final density distribution is in good agreement with the experiments. The experiments show a sharp increase of density at the powder layer in contact with the top and bottom punches. The numerical model, with the discretization level used, was not able to predict this effect.

Fig. 31 Density distribution along axis of cylindrical bushing: FEA predictions versus experimental results

This article has examined the general structure of constitutive laws for the compaction of powder compacts and demonstrated how these material models can be used to model the response of real world components to a series of complex die operations. It identified the general structure of the constitutive law and described a number of models that have been proposed in the literature. This field is still evolving, and it is evident that there will be significant developments in this area over the next few years as a wider range of experimental studies are conducted, providing greater insights into the compaction process. At the current time, there is no universally accepted model. Therefore, a pragmatic approach and a relatively simple form of empirical model were adopted requiring, for the determination of the unknown functions, a limited range of experiments. This selection allowed an examination of the compaction of axisymmetric components in detail and a comparison of general features of the component response with practical measurements. Similar procedures could have been adopted for any of the methods described, although in general, more sophisticated experiments are required in order to determine any unknown function or coefficients, particularly if the shape of the yield function is not known, or assumed, a priori.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Introduction

POWDER METAL COMPACTING PRESSES, equipped with appropriate tooling, frequently are used for producing P/M components. Although commonly called P/M presses, use is not limited to the pressing of metal powders. Almost any alloy or mixture of materials produced in powder form can be compacted into suitable end products. The majority of components fabricated by P/M presses, in number of pieces and pounds of product produced, consists of compacted metals. Ferrous-base metals constitute the largest usage. Powder metallurgy compacting presses usually are mechanically or hydraulically driven, but they can incorporate a combination of mechanically, hydraulically, and pneumatically driven systems.

Table 1 summarizes some of the developments for P/M presses in the last 40 years. Other recent improvements in compaction technology include:

- Split-die techniques to make multilevel parts having different peripheral contours at different levels
- Punch rotation capability to facilitate production of helical gears and other helical shapes
- Higher compaction pressures by using stronger tool materials, advanced pressure control methods, and die wall lubricants
- Better process control with computerized tool motion monitoring
- Warm compaction and improved "segregation-free" powders with enhanced flow characteristics

Table 1 History of development in P/M presses

Years	Compacting press
1955-1959	Cam press, HP
1960-1964	Toggle press, MP
1965-1969	Large size HP (500 +), large size MP (500 +)
1970-1974	Multisteped MP, double die compacting press
1975-1979	Large size MP (750 +), tool holder quick change
1980-1989	NC press, multisteped HP (800 +), large size rotary press
1990-1994	Large size MP, automatic P/M manufacturing line
1995-present	Hybrid (mechanical/hydraulic) presses (800 tons)

HP, hydraulic press; MP, mechanical press; NC, numeric controlled

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Compacting Press Requirements

Although P/M presses resemble stamping and forming presses, several significant differences exist. Press frames generally have straight sides. Gap-type or "C" frame presses are not suitable because the frame deflects in an arc under load, resulting in a slight out-of-alignment condition between the bed and side of the press. This arrangement produces a compacted part that is slightly out of parallel, top to bottom. Because P/M tooling clearances are generally ~ 0.025 mm/25 mm (0.001 in./1 in.) total, bending deflection can cause broken tooling or excessive tool wear.

Powder metallurgy presses apply sufficient pressure from one or both pressing directions (top and bottom) to achieve uniform density throughout the compact. Design should include provision for ejecting the part from the tooling. Pressing and ejection occur during each cycle of the press and must be accurately synchronized.

Presses need sufficient connected horsepower to compact and eject the part. In most press-working applications, the working stroke is a small portion of the total stroke of the press. In P/M presses, the working stroke during the compaction portion of the cycle is usually greater than the length of the part being produced, and the ejection portion of the cycle has a working stroke equal to or greater than the length of the part by a factor of approximately two or three. In some cases, the power required during the ejection cycle is greater than that required during compaction.

Presses should provide for adjustable die filling (the amount of loose powder in the tooling cavity). Automatic powder feeding systems that are synchronized with the compaction and ejection portion of the press cycle are desirable. Finally, P/M presses must meet federal, state, and local design and construction safety laws. Metal Powder Industries Federation (MPIF) standard 47 details safety standards for P/M presses.

Mechanical presses are available in top-drive and bottom-drive arrangements. In top-drive presses, the motor, flywheel, and gearing system are located in the crown or upper structure of the press. Presses with pressing capacities of ~ 1780 kN (200 tons) are floor mounted, requiring little or no pit. Top-drive presses with pressing capacities >1780 kN (200 tons) usually require a pit to maintain a convenient working height for the operator.

In bottom-drive presses, the drive mechanism, motor, and flywheel are located in the bed of the press. These presses usually are "pulled down"; that is, the top ram of the press is pulled downward by draw bars or tie rods. Bottom-drive presses with pressing capacities of >445 kN (50 tons) usually require pits. Top-drive and bottom-drive presses are comparable in terms of partmaking capability, reliability, and equipment cost.

Press Tonnage and Stroke Capacity. Required press capacity to produce compacts in rigid dies at a given pressure depends on the size of the part to be pressed and the desired green density of the part, which in turn is determined by requirements for mechanical and physical properties of the sintered part. Compacting pressures can be as low as 70 to 140 MPa (5 to 10 tsi) for tungsten powder compacts or as high as 550 to 830 MPa (40 to 60 tsi) for high-density steel parts.

When a part is pressed from the top and bottom simultaneously, the press should apply the required load to the upper and lower ram of the press. To eject the pressed compact, an ejection capacity must be available that is sometimes divided into the load for the breakaway stroke (which is the first 1 to 12 mm ($\frac{1}{32}$ to $\frac{1}{2}$ in.) of the ejection stroke and the load for a sustained stroke). The load for a sustained stroke is generally one-fourth to one-half of the breakaway load.

The stroke capacity of a press, or the maximum ram travel, determines the length of a part that can be pressed and ejected. In presses used for automatic compacting, the stroke capacity is related to the length available for die fill and ejection stroke.

Load Requirements. The total load required for a part is determined by the product of the pressure needed to compact the part to the required density and the projected area of the part. Compaction curves relate pressure, P , to the required density, q , and are usually obtained from compacting tests on cylindrical shapes with the height, L , equal to the diameter,

D. For thicker parts the load must be increased, by as much as 25% for a length to diameter ratio of 4 to 1, to give the required density.

Required compacting pressures can be estimated with a correction factor, k , such that (Ref 1):

$$P = P_1 (1 + k)$$

where P is the compaction pressure for a larger part and P_1 is the compaction pressure for a "standard" part (i.e., $L = D$). The correction factor is:

$$k = (0.25/3)(L/D - 1) \text{ for } L/D > 1$$
$$k = 0 \text{ for } L/D < 1$$

For parts that are not cylindrical, an equivalent L/D ratio can be used:

$$L_e/D_e = (V \cdot p)/(2 \cdot A^2)$$

where V is the part volume and A is the projected area. The press load required is then obtained by multiplying the required compaction pressure by the projected area of the part.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Mechanical Presses

In most mechanical P/M compacting presses, electric motor-driven flywheels supply the main source of energy used for compacting and ejecting the part. The flywheel normally is mounted on a high-speed shaft and rotates continuously. A clutch and a brake mounted on the flywheel shaft initiate and stop the press stroke. To initiate a press stroke, the brake is disengaged and the clutch is engaged, causing the energy stored in the rotating flywheel to transmit torque through the press gearing to the final drive or press ram.

Clutch and brake systems should be of the partial revolution type that can be engaged and disengaged at any point in the pressing cycle. The clutch usually is pneumatically engaged with a spring release, and the brake is pneumatically released with a spring set, thereby providing full stopping ability in the event of loss of air pressure. An adjustable speed device normally is supplied with electric drive motor, providing production rate adjustment as indicated by pressing and ejection conditions.

On presses that have main motor capacities up to ~ 19 kW (25 hp), the adjustable speed drive is usually of the variable-pitch pulley or traction-drive type. Above 19 kW (25 hp), direct-current or eddy-current control devices are preferred. The motor and drive must be totally enclosed to prevent contamination by metal powder dust.

Gearing systems usually are either single-reduction (Fig. 1) or double-reduction (Fig. 2) arrangements. Single-reduction gearing frequently is used in lower tonnage presses (≤ 445 kN, or 50 tons) that have stroking rates of ~ 50 strokes/min. Higher tonnage presses use double-reduction gearing and commonly have maximum stroking rates of 30 strokes/min.

Fig. 1 Single-reduction gearing systems for P/M compacting press

Fig. 2 Double-reduction gearing systems for P/M compacting press

The low-speed shaft of the press, normally called the main shaft, is linked to the press ram, causing motion of the tooling for the compacting and ejection cycles. Ram driving mechanisms can be either cam- or eccentric-driven arrangements.

Cam-driven presses generally are limited to pressing capacities ≤ 890 kN (100 tons). The main shaft of the press has two cams--one cam operates the upper ram, and the other cam operates the lower ram for compacting the part. The cam that operates the lower ram also controls the powder feed into the die and ejects the part from the die after compacting. Cams normally operate linkages that convert the main shaft rotary motion into the linear motion of the tooling.

Figure 3 shows a schematic of a cam-driven press. The cams in this type of press can be adjusted or arranged with removable sections, thus allowing cam motion to be varied to produce special motions to compact the part. Pressure can be applied either simultaneously or sequentially to the top and bottom of the compact. Anvil and rotary presses are types of cam-driven machines. These presses are described in more detail later in this article.

Fig. 3 Schematic of cam-driven compacting press

Eccentric-Driven Presses. Presses that have a final drive mechanism consisting of an eccentric or crank on the main shaft are the most widely used type of mechanical press. A connecting rod is used to convert the rotary motion of the main shaft into the reciprocating motion of the press ram. Generally, an adjustment mechanism is built into the connecting rod or press ram assembly, thus permitting the height position of the press ram to be changed with respect to the main shaft or press frame, thereby controlling the final pressing position of the ram. This adjustment mechanism can be used to control the length of the compacted part. Standard eccentric-driven presses have pressing capacities ranging from 6.7 to 7830 kN (0.75 to 880 tons).

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Hydraulic Presses

Hydraulically driven compacting presses are available with pressing capacities ranging from 445 to 11,100 kN (50 to 1250 tons) as standard production machines, although special machines with capacities $\leq 44,500$ kN (5000 tons) have been used in production. Hydraulic presses normally can produce longer parts in the direction of pressing than mechanical presses, and longer stroke hydraulic machines are less expensive compared to an equivalent stroke produced in a mechanical press. The maximum depth of powder fill in mechanical presses is ~ 180 mm (7 in.), while 380 mm (15 in.) of powder fill is common in hydraulic presses.

The maximum production rate for hydraulic presses producing a single part per stroke is ~ 650 pieces per hour. The slower speed of a hydraulic press when pressing long parts is preferable, because the longer time during pressing permits trapped air within the powder to escape through the tooling clearances.

Most hydraulic presses are considered top-drive machines because the main operating cylinder is centrally located in the top of the press. This main cylinder provides the force for compacting the part. Hydraulic presses have three distinct downward speeds:

- *Rapid advance:* Produces minimal pressing force, used for rapid closing of the die cavity
- *Medium speed:* Pressing capacities $\sim 50\%$ of full-rated capacity, used during initial compaction when lower pressing force is required

- *Slow speed:* Maximum capacity available for final compaction

Two types of hydraulic pumping systems are commonly found in P/M presses: the high-low system and the filling circuit system. The high-low system has a double-acting main cylinder. A regenerative circuit is used for rapid approach. Initially, the piston of the cylinder is activated by a high-volume, low-pressure pump; the fluid from the bottom of the cylinder is directed into the top of the cylinder in addition to the low-pressure pump volume. At medium speed, the regenerative circuit is deactivated, while the piston remains activated by the low-pressure pump. In full-tonnage press, the low-pressure pump is deactivated, and a high-pressure pump activates the piston.

The filling circuit hydraulic pumping system has a single-acting main cylinder, and ram motion is controlled by small double-acting cylinders. The ram control cylinders are smaller than the main cylinder, so only a low flow rate of fluid is needed to cause rapid movement of the ram. During approach and return cycles, however, the fluid flow rate into and out of the main cylinder is high. The main cylinder is fitted with a large two-way valve that allows fluid to flow at low pressures (usually gravity feed). During pressing, the two-way valve is closed, and high pressure from the pump is applied to the main cylinder piston.

Ejection of the part usually is accomplished by a cylinder that is centrally located in the bed of the press. The cylinder either upwardly ejects the part or pulls the die downward from the part, depending on the type of tooling used.

When pressing parts to a given thickness, positive mechanical stops are used on hydraulic presses to control downward ram movement. When pressing parts to a desired density, downward ram movement is controlled by adjustment of the pressure to the cylinder. When the part is pressed to the desired unit pressure, the press ram stops and returns to the retracted position. Some types of P/M materials, such as P/M friction materials, are always pressed to density rather than size, because uniform density provides uniform friction and wear properties.

The drive-motor horsepower on a hydraulic press is considerably larger than on an equivalent mechanical press. A mechanical press has a flywheel from which energy is taken during the pressing and ejection of the part. Energy is restored to the flywheel during the die feeding portion of the cycle. The motor on a hydraulic press must supply energy directly during the pressing and ejection portion of the cycle.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Comparison of Mechanical and Hydraulic Presses

In terms of partmaking capability, no distinct advantage is gained by using either a mechanical press or a hydraulic press. Any part can be produced to the same quality on either type of machine. However, the following parameters influence press drive selection.

Production Rate. A mechanical press produces parts at a rate one and one-half to five times that of a hydraulic press as a result of inherent design of the energy transfer systems and stroke length.

Operating cost of a hydraulic press is higher, because the total connected horsepower of a hydraulic press is one and one-half to two times that of an equivalent mechanical machine. Theoretically, the required energy to compact and eject a part is the same for a hydraulic or a mechanical press, except that the overall efficiency of a mechanical press is slightly higher than that of a hydraulic press. Also, the kilowatt usage of the larger motor on a hydraulic press is greater than that of a mechanical press during the idle portion of the machine cycle.

Machine overload protection is an inherent feature of a hydraulic press. If the hydraulic system is operating properly, the machine cannot create a force greater than the rated capacity. Consequently, overload of the machine frame is not possible, even if a double hit or operator error occurs in adjusting the machine. Misadjustment or double hits can cause a mechanical press to overload, can damage the machine, or may cause tooling overload and failure if the tooling

cannot withstand full machine capacity. Some new mechanical presses are equipped with hydraulic overload protection systems.

Equipment cost of a hydraulic press generally is one-half to three-quarters that of an equivalent mechanical press. Facility, foundation, installation, and floor space costs generally are comparable.

Die Sets. The mounting into which the tooling is installed is known as the die set. Generally, the die set must be well guided because of the close tooling clearances used. Guide bearings must be protected with boots or wipers to prevent powder particles from entering guiding surfaces. Tooling support team members should have high stiffness to minimize deflection.

The die set must be free of residual magnetism. The maximum acceptable level is ~ 2 G. To ensure press operator safety, die sets should be adequately guarded. In a complex tooling arrangement, as many as seven independent tooling members and supports are moving relative to one another during the pressing and ejection cycles.

Die sets can be classified as removable or nonremovable. Both types are used in mechanical and hydraulic presses. Nonremovable die sets are used throughout the entire tonnage requirements of available presses. Manually removable die sets are used primarily in presses with pressing capacities up to ~ 2670 kN (300 tons). Above this press size, the die set assembly is moved by a powered system, and removable die set presses with capacities of $\leq 17,800$ kN (2000 tons) are available.

The major advantage offered by nonremovable die sets is flexibility in setup and operation. Presses equipped with nonremovable die sets usually have all adjustments required for setup and operation built into the press and die set, including:

- *Part length adjustment:* Any dimensions of the part in the direction of pressing can be quickly changed during production.
- *Part weight:* Material weight in any level of the part can be changed easily during production.
- *Tooling length adjustment:* Adjustments are provided to accommodate shortening of punch length due to sharpening or refacing.
